the service of the military department to go on the continent. A British Field Hospital of 40 beds for Belgium has also been fitted up with every requisite for emergency work under the Red Cross, Belgian Branch. Five surgeons and 20 nurses form the medical staff, which is said to be honorary. The Research Hospital, Cambridge, has also been placed at the disposal of the War Department fully equipped and staffed for the care of 20 wounded officers. Nor is it at home alone that such offers are made, for the dominions are the seat of a similar upheaval caused by the war. India's ruling princes, always eager to place their wealth at the service of the empire, are adding contributions of hospitals and ambulances for wounded. Here is an example: The Delhi Medical Association offers the field hospital which was sent to Turkey during the Balkan war and Bengalee students are clamoring for the privilege of forming an ambulance corps. Donations to the Imperial Relief, the Prince of Wales Fund, the Indian Relief Fund, and other forms of assistance are being announced on the most generous scales for the victims of the war and their dependents.

The Chadwick trustees announce their intention, under the authority of the trust, to award this year's Chadwick gold medal and a sum of £50 each to the military and naval medical officer respectively who shall have most distinguished himself in promoting the health of the men in the two services. The trustees also intend to promote series of lectures and demonstrations on naval, military and hospital hygiene.

Just over a fortnight will bring us to the opening of the next winter session at the medical schools and colleges, the 1st of October being the traditional "opening day" which almost all students as well as numerous teachers make a point of remembering. Many practitioners, too, are glad to look in at their old schools sometimes and the day is one of reunion of old acquaintances as well as of contemporaries. The winter session of six months duration—twice as long as the summer session—is moreover that in which new students begin their curriculum and this is a circumstance which interests the lecturers at the colleges as well as the physicians and surgeons to the hospitals, for they may be spoken of collectively as the teachers, and besides their fees for teaching they are naturally concerned with the prosperity of the institutions they serve. So it is that already we are looking forward to "our opening day" and even this terrible war does not hinder us when we casually meet from exchanging opinions as to the probable number of new entries on the 1st proxim. at our several schools and hospitals. The prospectuses of all of the universities are already freely circulated, so that full information is at the service of every one desiring to ascertain the requirements for beginning the study of medicine and allied branches of knowledge, as well as the course to be pursued and the examinations to be passed in order to be placed on the *Medical Register* as authorized to practise the profession.

The *Register* is kept by the General Medical Council, a body established by Parliament in 1858 and comprising representatives of the universities and other corporations which were entitled to grant diplomas in medicine, as well as of actual practitioners of the government.

The power of removing a name from the *Register* in case of certain serious offenses gives the Council control over the profession which has, on the whole, been reasonably exercised. To the Council is also committed similar powers in regard to dentists and a separate *Dental Register* is kept.

The death is announced of Dr. Walter Holbrook Gaskell, F.R.S., LL.D., Fellow of Trinity Hall, Cambridge, and University Lecturer on Advanced Physiology since 1883. He was Marshall Hall Prizeman of the Royal Medical and Chirurgical Society in 1888, and in the next year took the gold medal of the Royal Society. He was also Baly medallist of the Royal College of Physicians.

The death has also occurred of Lt.-Col. R. W. Barnes, late of the R. A. M. C., who joined the service in 1880, was in the Nile Expedition of 1898, for which he was mentioned in dispatches, and received two medals with clasp. In the South African war in 1899-1900 he was in charge of a general hospital, for which he was awarded the Queen's medal with two clasps. He retired in 1900.

7. What the City Should Do to Control Syphilis. T. B. Shea.

5. Syphilis of the Lung.—E. A. Burnham concludes that syphilis produces in the lung pathological changes which in turn cause symptoms and physical signs which are identical with those produced by pulmonary tuberculosis. The two conditions are confounded by our most skilled diagnosticians. Great injustice is done the patient and great suffering is often inflicted upon his family by sending cases with lung syphilis to tuberculosis sanatoria. Greater care must be exercised in differentiating the two conditions, and especially those cases where there are signs of infiltration and open lesions in which tubercle bacilli cannot be demonstrated.

6. The Relation of Syphilis to Internal Medicine.—D. L. Edsall states that the results of the recent large experience in Wassermann reactions in the medical wards of the Massachusetts General Hospital show in consonance with the experience of other clinics elsewhere, the much greater frequency of gastrointestinal manifestations of syphilis than has been thought, until very recent years. If one includes the cases in which the symptoms were abdominal and apparently referable to the digestive tract, there were 46 cases in which the clinical manifestations were digestive. There were eight cases of nephritis with a positive Wassermann reaction. What the relation of the syphilis to the nephritis was is still too confused a question to make it profitable to discuss it here. There were four cases with very marked splenomegaly as the main manifestation and a number of others in which there was usually marked splenic enlargement in association with liver disease, these cases emphasizing again the important role of syphilis in splenomegaly. There were four cases in which unusually marked intestinal adhesions occurred after operation in persons who had syphilis. There is another group of cases including three of visceroptosis and neurasthenia and three of simple general neurasthenic symptoms, in one of the latter associated with marked inanition. All those with visceroptosis apparently developed their neurasthenic symptoms after the syphilitic infection and in the three

cases with debility there was no other explanation of the condition than the syphilis. One may at time see the most unusual manifestation of syphilis and may be unable in the end to say what was the matter excepting in general that the patient had syphilis. For instance, a colored man was admitted to the ward with a diagnosis of tuberculous peritonitis and had marked loss of weight, slight irregular fever, vague pains in various parts of the abdomen, a somewhat prominent and boggy feeling abdomen, and did appear to have peritoneal tuberculosis. But he had a positive Wassermann and upon treatment almost immediately got entirely well.

2. The Paraffin Treatment of Constipation.—J. H. Kellogg enumerates the virtues of paraffin oil as follows: It lubricates the alimentary canal throughout its whole length. This mechanical action is highly important in overcoming kinks due to redundancy or to Jackson's membrane, and adhesions resulting from colitis or other causes. The human alimentary canal, like that of other primates as illustrated in the diet of the higher apes, is adapted to a moderately coarse bill of fare. The concentrated diet of modern civilized life contains so little indigestible material that the residue forms a pasty mass which tends to adhere to the intestinal wall, especially when any obstruction is caused by kinks, folds, adhesive bands, or a spastic state of the bowel due to colitis. When delay occurs the further absorption of water converts these pasty residues into hard masses, scybala, which sometimes have almost the density of wood. Fats of all sorts are more or less laxative if taken in sufficient amount, through their effect in modifying the character of the food residues. Paraffin is useful in all forms of intestinal stasis no matter what the cause, by preventing the abnormal drying out of the food residues which is the necessary result of too long retention in contact with absorbing surfaces. Another remarkably interesting and useful property of paraffin oil is found in the fact that it stimulates the activity of the small intestine. Paraffin oil, itself not absorbable, takes up a very considerable portion of the toxins found present in the intestinal tract and thus prevents their absorption. When paraffin is used, it may always be seen in the stools, showing a brownish or blackish color, due to the substances it holds in solution. Paraffin oil serves a useful purpose in protecting the mucous membrane when it is in an irritated state, as in cases of chronic colitis. Paraffin serves another useful protective purpose in hindering the absorption of poisons by mucous surfaces which have been deprived of their epithelium. In cases of colitis paraffin oil protects the irritated surfaces, but also through its lubricating effect and through softening the intestinal contents, aids greatly in overcoming the spastic condition of the intestine, which in many cases of chronic constipation is so formidable an obstacle to recovery. Incompetency of the ileocolic valve is a most common and effective cause of iliac stasis. Aside from the regulation of diet, the regular use of paraffin oil is the most effective means of combating this condition. In cases in which the iliac stasis is due to spasm of the ileocecal valve, induced by chronic appendicitis, ovarian irritation or inflammation, colitis, or possibly painful rectal disease through reflex irritation, paraffin proves itself to be an invaluable remedy, since it has the property of increasing the peristaltic activity of the small intestine to such a degree as to enable it to overcome the spasm of the ileocecal valve without producing irritation, which would inevitably increase the spasm of the sphincter as do drug laxatives. Paraffin is capable of rendering invaluable service in cases of intestinal intoxication by increasing the number of daily stools.

4. Gastric Ulcer and Its Surgical Treatment.—C. G. Cumston states that gastric ulcer has undoubtedly a natural tendency to heal, and proper medical treatment gives satisfactory results in the majority of uncomplicated cases. Although medical treatment should always be tried first and often is quite successful, it is none the less true that sometimes it utterly fails and that there exist ulcers which are rebellious to treatment. It is in these instances that the surgeon comes into play, and two methods are at one's disposal, namely, the radical and the palliative interferences. The radical method is resection of the ulcer. Excision of the diseased part is evidently the ideal treatment, and has considerable advantages theoretically, such as complete removal of the lesion and the impossibility of malignant transformation taking place in the ulcer. But in reality the cure is not as permanent as at first sight it would seem. In the first place, the ulcer is only single in about twenty per cent. of the cases, in the remaining eighty per cent. it is mutiple, and when a single ulcer is resected, one can never be certain, even after a careful exploration of the interior of the stomach, not to overlook another, so that the resection of one does not prevent the evolution of another which has escaped the operator's notice. Then, too, resection of the ulcer hardly changes the causes to which it is due nor the soil on which it has developed, so that there is nothing astonishing in the fact that a new ulcer develops after the operation. Resection of a gastric ulcer is a difficult procedure and is rarely possible under good circumstances, because the absolutely essential condition for a successful resection is an easy mobilization of the stomach. After resection of the lesion and suture of the stomach, the loss of tissue may be such that the organ is deformed and its motor functions considerably interfered with. The thick adhesions often conceal from view small abscesses, the rupture of which can readily infect the peritoneal cavity, thus adding another danger to the operation. There remains the palliative method. This has for its object, not the elimination of the ulcer, but the creation of conditions favorable for its rapid cicatrization. Two quite different operations attain this result, namely, gastroenterostomy and jejunostomy. Gastric ulcer is to be divided into two groups, viz., ulcers seated in the pyloric region and pylorus, and secondly, ulcers in any other part of the stomach, including the cardiac region. The first class is the only one where gastroenterostomy is indicated, while the second should be treated by jejunostomy. Gastroenterostomy sets up changes in the gastric chemistry, which without any doubt result in a favorable healing influence for the ulcer. It diminishes the gastric hypersecretion and hyperacidity, the principal factor being the mixture of the bile and pancreatic juice with the gastric juice, by reflux of the former into the stomach. Ulcers situated far from the pylorus should never be treated by gastroenter-

ostomy, which should be reserved for pyloric lesions only, if the surgeon does not wish to have a poor therapeutic result or one which is nil. When the ulcer is not pyloric jejunostomy by the Eiselsberg-Wizel technique, the only one to be employed is the only proper interference, and it may be laid down as an axiom that the nearer the ulcer is to the cardia, the greater is the contraindication to gastroenterostomy and an absolute indication for jejunostomy. Among the symptoms which endanger life, hemorrhage is the first to be considered, and here the author refers to serious hemorrhage, because any operative interference is here contraindicated and medical treatment gives far more hope. This does not apply to slight hematemisis, however, which recurs at frequent intervals, and if it is not permanently stopped by medical treatment, it is a sufficient argument for surgical treatment. Under these circumstances it is wiser and more prudent to resort to jejunostomy without waiting for the development of more serious trouble. Progressive loss of flesh is another important symptom. The loss of weight should not be allowed to go too far, first, because a weakened organism is in poor condition for defense and repairs its lesions with difficulty; secondly, because the ulcer markedly undermines the organism and thus favors the development of tuberculous infection or the appearance of a latent tuberculosis. There are also cases of gastric ulcer, in which gastric intolerance is absolute, and severe pain is produced by taking food. Absolute rest of the stomach is here particularly necessary, so that jejunostomy is clearly indicated. In the simple types of acute gastric ulcer, the medical treatment which is easily carried out, should rapidly show results. But if medical treatment is of no avail, then jejunostomy is to be recommended without hesitation. This operation is even more imperative when the social position of the patient precludes proper medical treatment. Jejunostomy will also be advantageously applied in those cases where gastroenterostomy is indicated, but where the physical condition of the patient is at a low ebb. Again in all cases where gastroenterostomy is unwise, although feasible on account of the local condition, jejunostomy has its field of usefulness, likewise in cases where gastroenterostomy has already been done and failed in its results.

2. The Newer Bacteriology of Various Infections as Determined by Special Methods.—By E. C. Rosenow. (See MEDICAL RECORD, July 4, 1914, page 35.)

3. Gastrointestinal Studies.—M. E. Rehfuss, O. Bergeim, and P. B. Hawk have employed a method by which it is possible to follow the entire cycle of gastric digestion with practically no discomfort, and by which it is possible at any given moment to draw off any or all of the juice secreted in sufficient quantity to perform the necessary chemical examinations. They have pointed out the inadequacy of the ordinary stomach-tube and have substantiated the statements of Harmer and Dodd that the stomach-tube does not remove completely the gastric contents. The principle of the authors' tube is entirely that of gravity, and the tip is sufficiently heavy to seek the lowest portion of the stomach. Furthermore, it is slotted in such a way as to permit the aspiration of a representative sample of the gastric juice. These perforations represent the maximum bore of the rubber tubing. The instrument is inserted and left in the stomach for hours until the gastric cycle is completed. The authors conclude that by means of their modified gastric tube, they can study the entire cycle of gastric digestion, recording both the secretory and motor activity. They can construct a curve which graphically records the entire course of digestion. Information as to the amount of the secretion can be obtained at any point by complete aspiration and by the character of the specimens which are obtained. There is no specific curve for the normal person, but three types of curve can be found depending on the rapidity of reaction to a given stimulus, the height of the curve, and the descent of the curve. These types may be termed, respectively, the hypersecretory, the hyposecretory, and isosecretory types, depending on their respective reaction to such stimuli. Figures approximating those commonly regarded as hyperacidity are to be found in some period of the curve in a large number of normal persons. A "continued" secretion is described in normal persons which is intimately linked with alimentary and chronic hypersecretion, but can be distinguished from them. The value of this method in various pathological states is emphasized and a limited number of cases are reported together with their findings. The technique commonly employed for estimating gastric function is entirely inadequate, inasmuch as it indicates but one phase in a constantly changing cycle, and that phase is by no means always the high point in the digestive curve. The authors would insist on the great advantages of this method which, correlated with the various tests performed on different samples as well as the special tests described elsewhere, enables them to make a more perfect study of the digestive cycle than has hitherto been possible.

5. A Study of the Arneth Formula.—By Graham E. Henson. (See MEDICAL RECORD, July 4, 1914, page 37.)

7. The Diet in Typhoid Fever.—Lewellys F. Barker states that one should bear in mind a point emphasized by Coleman, namely, the necessity of beginning cautiously, and gradually increasing the caloric value of the intake. The plan Coleman recommends is to give a pure milk diet for two days in all cases. If the patient be very ill, he may be kept, thereafter, on a fluid diet of from 1,000 calories (1 liter milk, 50 c.c. cream, 50 grams lactose divided into eight feedings), up to 3,900 calories (1.5 liters milk, 0.5 liter cream, and a pound of lactose, divided also into eight doses) in the twenty-four hours. Soft boiled or scrambled eggs may be added to this diet even when patients are quite sick. In mild cases, the patients may from the beginning take, in addition, buttered toast, mashed potatoes, and cereals in amounts sufficient to make the total caloric intake 4,000 per day. In convalescence 5,000 or 6,000 calories per day may often be given. The careful analysis of the patients in Bellevue Hospital showed a lower mortality among the patients fed on

the high-calory diet than among the other cases. Complications (hemorrhage; perforation) and relapses were no more frequent than in patients fed in the old way. The greater gain from the liberal diet consists in the lessening of emaciation, the shortening of convalescence, and the prevention of exhaustion phenomena after the disease has run its course. Most patients lose 5 or 10 pounds even on the high-calory diet, though now and then a patient can maintain his weight. In the Johns Hopkins Hospital the author and his associates have been struck with the better appearance of their patients during convalescence since they have fed their patients more liberally. Since convalescence can be shortened, and emaciation prevented, there is good reason to believe that posttyphoidal psychosis and posttyphoidal neurasthenic states will be less common than under the old regimen.

8. Effects of Food on Metabolism in Typhoid Fever.—Warren Coleman concludes that food does not increase the heat production or the temperature in typhoid fever, even when given in large amounts (at least, when the quantity of protein is kept relatively low). Therefore, the fear which has been entertained by physicians for so many years that a liberal diet would raise the temperature of the patient is proved to be groundless. The body utilizes carbohydrate in preference to fat or protein to meet the increased demand for energy in typhoid fever just as it does in health when called on to perform additional work. Consequently, carbohydrate should occupy a prominent place in the diet.

9. The Psychosis of Pernicious Anemia.—G. H. Williams reports the cases of two patients suffering from well defined pernicious anemia, who showed in common many mental signs, namely, lack of orientation—in the one case in every field, and in the other especially in regard to place; lack of insight; such delusions as one commonly meets in paranoid states—those of a persecutory type; the memory in one case apparently normal, until late in the condition, while in the other there was lack of accuracy for both recent and remote events; the mood in both parties much happier than the physical condition would warrant; lack of attention and appreciation, and numerous physical signs such as parasthesias, diminished sensibilities, vertigo, speech disturbances, loss of functions of the arms and legs, ankle-clonus, unequal patellar reflexes, Romberg signs, unsteady gait. Apart from the abnormal mental conditions present it is evident that one is dealing with some lesions of the brain and spinal cord, such as have been described by various writers in their reports of cases.

5. A Case of Congenital Atresia of the Bile-Ducts. S. Wyard.

1. Heredity in Man.—W. Bateson points out that potentialities and aptitudes, physical as well as mental—sex, colors, powers of work or invention, liability to diseases, possible duration of life, and the other features by which the members of a mixed population differ from each other—are determined from the moment of fertilization. The clearest evidence of regularity in the inheritance of human characteristics has been obtained in regard to the descent of marked abnormalities of structure and congenital diseases. As to the descent of hereditary diseases and malformations, however, one has abundant data for deciding that many are transmitted as dominants and a few as recessives. The most remarkable collection of these data is to be found in family histories of diseases of the eye. Neurology and dermatology have also contributed many very instructive pedigrees. The greatest practical change likely to ensue from modern genetic discovery would be a quickening of interest in the true nature of man and in the biology of races. The remedies proposed in America, in so far as they aim at the eugenic regulation of marriage on a comprehensive scale, have been devised without regard to the needs either of individuals or of the modern state. The definitely feeble-minded one may with propriety restrain, and one may safely prevent unions in which both parties are defective, for the evidence shows that, as a rule, such marriages, though often prolific, commonly produce no normal children at all. In the study of history biological treatment is only beginning to be applied. The causes of the success and the failure of races are physiological events, and the progress of man has depended upon a chain of these events, like those which have resulted in the "improvement" of the domesticated animals and plants. How has that progress in control of nature which one calls civilization been achieved? By the sporadic appearance of variations, mostly, perhaps all, consisting in a loss of elements, which inhibit the free working of the mind. Annul the work of a few hundreds of men, and on what plane of civilization should one be? One should not have advanced beyond the medieval stage without printing, chemistry, steam, electricity, or surgery worthy the name. These things are the contributions of a few excessively rare minds. Galton reckoned those to whom the term "illustrious" might be applied as one in a million. In the light of Mendelian knowledge the discussion whether a race is pure or mixed loses almost all significance. A race is pure if it breeds pure and not otherwise. Historically one may know that a race like the English was, as a matter of fact, of mixed origin. But a character may have been introduced by a single individual, though subsequently it becomes common to the race. A population like the English indeed owes much of its strength to the extreme diversity of its components, for they contribute a corresponding abundance of aptitudes. Everything turns on the nature of the ingredients brought in, and these genetic disturbances lead ultimately to great and usually unforeseen changes in the nature of the population. External changes may indeed give an opportunity to special strains which then acquire ascendency. The industrial developments which began at the end of the eighteenth century, for instance, gave a chance to strains till then submerged, and their success involved the decay of most of the old aristocratic families. In all practical schemes for social reform the congenital diversity, the essential polymorphism of all civilized communities must be recognized as a fundamental fact, and reformers should rather direct their efforts to facilitating and rectifying class distinctions than to any futile attempt to abolish them. To the naturalist the broad lines of solution of the problems of social discontent are evident. They lie neither in vain dreams of a mystical and disintegrating equality, nor in the promotion of the malignant individualism which in older civilizations has threatened mortification of the humbler organs, but rather in a physiological coordination of the constituent parts of the social organism.

2. The Diagnostic Value of the Complement Fixation Reaction in Tuberculosis.—J. McIntosh, P. Fildes, and J. A. D. Radcliffe state that from a study of the literature dealing with complement fixation in tuberculosis it is clear that great diversity has been obtained in the results, while few have published series of cases of sufficient magnitude or sufficiently controlled to allow

of exact deductions. The chief cause for the diversity in the results is the composition of the antigen used. It was not appreciated by the earlier writers that an antigen consisting of old tuberculin was not analogous to an emulsion of tubercle bacilli. In fact, the antisubstances to these antigens are entirely different. The authors' technique which they have employed in carrying out the tests resembles in principle that which they have elaborated for the Wassermann reaction. As an indicator they have used both sheep and ox corpuscles, and have found the latter to be of advantage when the test serum contains an excess of the so-called normal amboceptor for sheep's corpuscles. The only reagent which requires special mention is the antigen. After a series of experiments in which various tuberculins and preparations of tubercle bacilli were tested it was found that a simple emulsion of living tubercle bacilli gave the best results. Every strain of tubercle bacilli is not suitable to act as an antigen. The strain employed in the tests was of the human type isolated from a case of phthisis, and was grown on Dorset's egg medium, on which it produced a more or less diffuse growth in from seven to ten days. It is found that a most trivial lesion which may even be overlooked in the post-morten room will give a positive Wassermann reaction but in the case of tuberculosis the lesion must be of considerable dimensions before the reaction can detect it. A caseous bronchial gland will not give a positive reaction; indeed, the common affections of the cervical glands will usually yield a negative result. On the whole one has come to the conclusion that a lesion in order to give a positive result must be of such dimensions as to constitute disease, and require the intervention of the physician or surgeon. One therefore looks upon the positive reaction as indicating active tuberculosis. It will thus follow that the complement fixation test is of much greater value than the cutaneous reaction, for instance. This latter indicates a state of hypersusceptibility to tubercle, and such a state may be present even though the lesion is quiescent or cured. It is no indication of active tuberculosis. When a particular condition is under examination and is suspected of being tuberculous a positive von Pirquet reaction will be of relatively little value, since so many adults are sufficiently tuberculous to give a positive result. A positive complement fixation will, however, strongly support the suggestion that the condition is tuberculous because it indicates active tubercle. As regards the value of the reaction in the diagnosis of pulmonary tuberculosis, the author concludes that in such suspected cases, a positive finding is of considerable value in establishing a diagnosis.

3. **Sepsis in the Recognition and Nonrecognition of Syphilis.**—E. M. Corner alludes to the very great importance of sepsis as a complicating factor in the pathological and clinical manifestations of syphilis. An aseptic condition of a primary sore may so mask its nature as to render it and the bubo quite unrecognizable; its nature may be suspected from its slowness in healing, its pathology may be proved by the demonstration of the presence of the spirocheta pallida. In the secondary stage of syphilis, it has long been recognized that an additional septic infection makes the secondary symptoms and signs very much worse. In the more cleanly classes of the community syphilis can be quite overlooked or not recognized in its primary, secondary or tertiary stage, and consequently its transmission may be unchecked and its dissemination unimpeded.

1. Dysentery. F. M. Sandwith.
2. Bullet Wounds in War. W. G. Tottenham Posnett.
3. On Some Signs and Symptoms of Hypothyroidism in School Children. J. Lawson Dick.

1. **Dysentery.**—F. M. Sandwith states that the history of the disease shows us that, almost more than any other infectious disorder, it has had a widespread diffusion all over the inhabited world; most countries have suffered from national visitations, and it is still true that wherever man is found some form of it is liable to appear. Since the Peloponnesian war there has hardly been a protracted military campaign in which dysentery has not scourged the hostile armies. To take only some modern instances: in the American Civil war the Federal troops lost 37,794 men from dysentery and diarrhea, which was nearly 30 per cent. of the total deaths; these diseases were also frightfully prevalent among the Federal prisoners at Andersonville, where they occasioned 50 per cent. of the sickness and 58.7 per cent. of the deaths from all causes. In the Franco-German war (1870-71) there were 38,652 admissions and 2,380 deaths from dysentery in the German army; the troops on their return home spread infection in many districts, some of which after all these years are not yet quite free from it. In the South African Campaign (1899-1902) there were 38,108 cases of dysentery with 1,342 deaths. Dysentery is now admitted to be water-borne. Dysentery can also be conveyed to man by contaminated food, by flies, and by human carriers. Even now it is not universally recognized that dysentery, under certain circumstances, is communicable from man to man, and that isolation is as necessary in this disease as in typhoid fever.

3. The Serum Diagnosis of Pregnancy and of Cancer: a Critical Study of Abderhalden's Method. A. Leitch.

3. **The Serum Diagnosis of Pregnancy and of Cancer.**—A. Leitch has come to the following conclusions after a careful investigation of Abderhalden's dialyzation method: The real fallacies of the technique are beyond control, and the hypothetical fallacies which Abderhalden invokes to account for false reactions have no bases. Positive results are quite well accounted for by the facts that the "substrates" alone, and the serums alone, give diffusible substances reacting with ninhydrin; that the dialyzers vary enormously in the quantities of such substances which they allow to pass in a given time; that serums, influenced by the distilled water and by the presence of a tissue acting by virtue of its physical state, are progressively cleaved, and that it is not the substrate which is split by the serum so much as the serum which is split by the substrate. These very real fallacies quite destroy the value of the method, and cast grave doubts on the whole theory. But it may pertinently be asked why one obtains such a large number of positive reactions in the serum of pregnancy in comparison to diseased conditions. It may be that regnant serum more commonly possesses the property of being split up when some suitable physical accessory is added, such as placental tissue. But what seems more probable is that there exists in serum, more frequently, though not exclusively, in pregnancy a *general* proteolytic and peptolytic power which one can demonstrate by adding a suitable, though not necessarily a *specific*, protein or peptone. The serum of the normal guinea-pig is generally credited with a fairly strong proteolytic power. The author tested the action of several guinea-pig serums on egg albumen, coagulated cancer tissue, human blood clot, and human placenta, and it happened that only with the latter were strong reactions evident. This seems to show that placental protein is a suitable

substrate for the demonstration of a general proteolytic power. Pincussohn and Petow found that the normal serum of each species of animal had a peptolytic power against the muscle peptones of that species only, whereas the serum of the guinea-pig had a peptolytic power against the muscle peptones of all other species tested. One may thus even admit that more in pregnancy than in other states the human serum may have a proteolytic and peptolytic power against the proteins of human tissue more than against other proteins; even that certain proteins, owing to their physical configuration, are more suitable than other for a demonstration of these enhanced powers; and yet one may condemn Abderhalden's whole theory of specific guardian ferments.

1. The Shockless Operation (Anoci-association).—H. M. W. Gray regards local anesthesia as the chief factor of any of those at our disposal in the prevention of pain and therefore of shock. Novocain, at all events in weak solutions of ¼ to ½ per cent., may be regarded as non-poisonous, having no deleterious action either at the site of application or on distant organs. Prevention of mental excitement or irritation is nearly as important as the prevention of pain. Too much time is occupied in the preparation of the patient. It is especially unnecessary and undesirable to keep a patient entirely confined to bed before most operations. One should learn lessons from emergency patients of all kinds in whom "preparation" is of the worst possible type, yet 70 to 90 per cent. of such cases recover with very little manifestations of shock. What is known nowadays as "carnivorous surgery" must be avoided. Cutting instruments must be sharp. Seizing large masses of tissue in pressure forceps, rough, sudden, or irregular retraction of wound surfaces, rough handling, tearing or pulling of tissues, especially of the parietal peritoneum or pleura, mesentery, and so forth, must be avoided as far as possible. In an abdominal operation conducted under local anesthesia alone, it is easy to appreciate that severe shock is readily produced by unskilled handling. It is also very appreciable how far shock may be completely avoided by well placed injections of local anesthetic in the abdominal parietes, mesentery, broad ligaments, etc., coupled with gentle treatment of the tissues. The use of local anesthesia demands that desirable delicacy of manipulation. The author emphasizes the importance of conserving heat and obviating irritation by the avoidance of undue exposure of abdominal viscera, raw surfaces, or even of large areas of the skin. Accurate and immediate hemostasis is more than desirable. Loss of even small quantities of blood may turn the scale in some patient. In abdominal cases the author believes that a firm binder has a beneficial effect during the first possible precarious hour or two. In view of numerous observations regarding changes produced by anesthetics in brain cells and their immediate and remote effects on the heart and other important organs and tissues, surely it is right to dispense with them as much as possible. This toxicity is greatest in the case of chloroform, ether stands next, while nitrous oxide has little deleterious effect when skilfully administered. The anesthetic is injected as follows: Five or six skin blebs are made with a fine needle and are infiltrated with a thicker, longer needle, along first the line of incision and then the lateral abdominal parietes, down to the peritoneum. If pain is made much of at this stage, the patient is given a small amount of ether, and if the operation is likely to entail difficult manipulation, he is given ¼ to ½ grain of a mixture of the alkaloids of opium. According to the length of the incision and the thickness of the abdominal wall, 100 to 200 c.c. may be used, After 10 to 15 minutes the operation may be begun. If pain is felt in the deeper layers, either a little more solution is injected locally or else wait for a few minutes longer. Further injections may have to be made into the peritoneal attachments of the organs which are to be operated on. As already stated a small amount of ether may have to be given at this stage, but need not usually be continued. When infiltrating the abdominal wall the solution should be injected as the needle is being pushed onwards, so that vessels and nerves, unless fixed in fibrous tissue, are floated aside. This will also cause the peritoneum and the fairly dense subperitoneal tissue immediately lining it to be carried in front of the solution, so that the looser part of the subperitoneal tissue is flooded with the solution. Diffusion of the fluid joins up the lines of punctures. Frequently in cases of appendicectomy, for example, the needle is pushed through the peritoneum, at the same time forcing out the anesthetic solution at greater speed, so that the bowel may be floated away from the point of the needle. During a severe operation, if the pulse tends to flag, especially if severe hemorrhage or previous sepsis has occurred, an intravenous or subcutaneous infusion of saline solution is the best restorative, unless direct transfusion of blood can be made.

1. Common Ailments in Camp.—Cecil Webb-Johnson states that it is a well-known fact that common ailments in camp are responsible for a great wastage of public money and a loss of training for a large percentage of men. It is known that the greater number of admissions to hospitals is among men between 20 and 25, and lowest among men between 40 and 50. This being the case, it is in the interest of the military authorities to pay especial attention to the young recruits, who should be questioned by their non-commissioned officer as to the state of their health during the first few days of camp life. The recruit is the last man to complain, because he is in the pristine state of enthusiasm and naturally wishes to appear as strong and capable as his comrades who have had more experience than himself. A very thorough examination of the mouth and throat should be made, for a man with bad teeth, enlarged tonsils, or adenoids generally gives trouble when in camp. The author thinks a man

may be rejected on general grounds, even if he is quite sound, for it is a well-known fact that certain men, although they pass according to the regulations, are not fitted for military service. All recruits should be medically examined before going to camp. One cannot be too strict in insisting upon the utmost cleanliness, not only in the person, but in camp generally. Whenever possible, the tents should be moved to fresh ground periodically, the length of time for the original tent ground depending on circumstances such as the weather, etc. Proper facilities should be given for hanging up all blankets and beddings, so that they can be sunned and aired. The author emphasizes the importance of every man having good serviceable boots and at least two pairs of good thick undarned socks. One of the greatest troubles in camp is blistered feet, and a large percentage of men are rendered unfit for duty for one or more days on this account. The next commonest minor ailment is gastric trouble. This takes various forms, including: (a) Constipation, (b) diarrhea, (c) vomiting, (d) colic. The change of air and food are responsible in a great measure for the constipation which is so common in camp life.

2. **Gangrene in War.**—C. M. Page had exceptional opportunities for the study of this subject during the late Balkan war. He classifies the types of gangrene seen under war conditions in accordance with their etiology, as follows: (1) Gangrene secondary to the interference with the blood flow through the main vessels of a limb. (2) Traumatic gangrene. (3) Infective gangrene. (4) Gangrene due to vasomotor paralysis. (5) Gangrene secondary to the effect of high explosives. The occurrence of the disease in young men with healthy circulatory systems is the one feature which is common to all these types, which feature differentiates them on the average from gangrene as met with in civil practice. This fact considerably affects the line of treatment and the prognosis. Gangrene of the extremities is occasionally seen as a result of direct slow velocity gunshot injury to the main brachial or femoral vessels; it more often occurs when a bone injury is present as well. In general, in this type of gangrene amputation can be carried out near the seat of injury and as soon as the process is definitely limited. In some instances, if the primary injury has not seriously involved the bone and is not infected, amputation at even a lower level may be safe. Traumatic gangrene is a term applied to a condition often indistinguishable from infective gangrene. Theoretically it is applied only to those cases in which death of a part result from direct injury, but it is evident that infection will be an important factor in the extent and progress of the condition. The treatment is practically the same as for the infective type. Acute infection with many organisims may cause some degree of local tissue necrosis. The term "infective gangrene," however, is usually reserved for those cases in which the process is definitely progressive and associated with toxemia. The cases of symmetrical gangrene which were seen in large numbers among the Turkish troops in the last months of 1912 resulted from a vasomotor disturbance. The gangrene was practically always symmetrical and affected the lower extremity in the brain of a spasmophile child is poor in lime in combut, as far as could be seen or learned, never independently of the feet. In cases in which the gangrene was moist and extending, or where signs of tetanus were present, amputation well above the lesion was carried out. The prognosis in this type of the condition was not favorable, as in addition to the pronounced toxemia the subjects were usually thoroughly exhausted from exposure and dysentery. When the gangrene was fairly dry the affected parts were powdered with boracic acid and left exposed to the air or lightly covered with wool; good food and stimulants then assisted the rapid formation of a line of separation. The author considered the condition to be strictly comparable to that of frostbite. The arterial circulation of the men affected was rendered extremely poor by the condition of starvation and fatigue; under these circumstances a temperature above freezing was able to produce stasis in the peripheral vessels. It is interesting to note that a strictly comparable condition attacked many of the English and French troops in the Crimean war. The mortality from this cause in the army which served in Bulgaria as well as in the Crimea was 33.3 per cent.; among the troops who only served in the Crimea it was 16.3 per cent. This enormous death rate was largely due to the complication of enteric diseases and typhus, which were both frequently acquired after the troops were admitted to hospital. Extensive gangrene of the extremities has been stated to occur in men after they have recovered from the effects of violent explosives. The only recent definite communication the author can find on the subject of this type of injury is by v. Berdisavljever, reporting from Servia; he says he saw cases of hematuria, hemothorax, and shock as the result of explosions, but he says that in no instance did he see gangrene. MacLean had under his care in Constantinople a remarkable case of gangrene of all four extremities attributed to this cause.

5. **Blindness in Children.**—N. B. Harman states that statistics based upon the study of eleven hundred blind children show that there has been a definite diminution of the incidence of cases of blindness caused by ophthalmia neonatorum, and it is reasonable to credit this diminution to the great efforts that have been made to prevent the disease during the past few years. The diminution is really greater than it appears by this method of tabulation, for the cases seen and accounted for in the first two counts are included within the last return. The apparent increase of the incidence of the cases of congenital syphilis is in part due to the diminution of the cases of ophthalmia, and in part to the use of finer methods of diagnosis, cases that formerly were tabled among those of "uncertain origin" are now definitely accounted for. It is certain that the number of cases of blindness due to ophthalmia is diminishing both actually and relatively to the causes of blindness. But there is not sufficient evidence to state certainly that the apparent increase of the syphilitic cases is due to any other cause than the diminution of one large class of case of blindness and the better means of diagnosis. The sum total of this examination of these blind children is the finding that more than one-half of them owe their miserable state of blindness to venereal disease of their parents.

6. **The Factor of Heredity in Myopia.**—J. A. Wilson points out that myopia is frequently hereditary, but the general opinion is that near-work—reading, writing and sewing—is the more important factor in its production, and the chief evidence for this opinion is the striking increase of myopia that occurs during school years. In a study of 1500 consecutive cases the author finds evidence of heredity in 58 per cent.; keratitis is classed as the cause of the myopia in 12 per cent.; and the cases in which evidence of heredity was unobtainable, constituted 30 per cent. When myopia is clearly hereditary, then it exists in all degrees—high and low—but low degrees are more frequently hereditary than high. High myopia makes its appearance before school work begins, and therefore must be due to heredity. It may be said that when the myopia is high the intensity of heredity has been

great, and that when the myopia is low the impulse of heredity has been less, and that near work or other suitable environment is necessary for the production of this variety, or to enable hereditary tendencies to become manifest. In the absence of this near work, or environment, the factor may lie dormant, skip a generation, or be only partially or fitfully expressed. When both parents are myopic then myopia is very prevalent among the offspring; it is less so when only one parent is myopic, and still less so when neither parent is affected. There is irregularity of incidence in individual families, but this is to be expected, as one or both parents may carry unexpressed the hereditary tendency to myopia, or one parent may be hypermetropic. When taken collectively this irregularity disappears. Among school children the sexes are found to be disproportionately affected, and this disproportion increases at and beyond the age of puberty, giving in the author's cases a ratio of two females to one male, a ratio that suggests sex-limitation. The incidence of myopia bears a direct relationship to the amount in the parentage, or extraction, and there is order in the transmission. There is similar evidence of heredity in high degrees and in low degrees of myopia and in the various occupations. There is no special association with any particular occupations, and all these innate characteristics indicate that the etiology of myopia is independent of environment.

Myoma and Pregnancy.—Landau states that despite the many successes in the treatment of myoma with mesothorium, radium and Röntgen rays we are often called on to treat these growths surgically. We do well, therefore, to group them according to indications and treatment. From this viewpoint there are four categories. In the first belong most uncomplicated cases, in which gestation occurs just as in the normal uterus. Any plan of active treatment is quite superfluous, even harmful. Growths of this type are often discovered by chance, both general and local symptoms of myoma having been absent. In the second category myoma causes such symptoms without or with pregnancy that an expectant policy is out of the question. Treatment, however, should be conservative, the growths being enucleated. The author has proceeded in this manner fourteen times. In some cases of enucleation of large myomata—the size of a man's fist—the women have continued to bear children, as many as five, all at term. In the third category pregnancy is not prejudiced, nor do the growths give rise to symptoms. The seat of the growth, the displacement of the uterus, or some other factor may, however, offer mechanical obstacles to delivery—for example, retrouterine or retrovesical myomata. The indication here is cesarean section, followed with total or supravaginal hysterectomy. Thus far there has been no mortality to mothers or children in the author's material. Finally, there is a fourth group in which pregnancy must be interrupted forthwith. On account of the distortion of the cervix uteri abortion is very largely out of the question, the indication being the same as in Group III. The Landau brothers have operated on 31 cases comprised under Group IV. During the past nine years they have performed 541 myomectomies and hysteromyomectomies. There were consecutive series of 152 and 131 cases respectively without mortality. In the entire material there were 51 cases of operation for myomatous gravid uterus—nearly 10 per cent.

Salvarsan Treatment and Latent Microbism.—Gutmann lays down the following rules of procedure in regard to salvarsan treatment. Acute febrile affections in the course of evolution with microbic latency are withdrawn from our cognition because of the total absence of symptoms. Now, since latent microbism conceals dangers, we must scrupulously adhere to the dictum of Gennerich that salvarsan should only be injected when the patient feels perfectly well. The therapeutist is then absolved from blame when, despite all pains, a collision between a salvarsan injection and latent microbism gives rise to more or less evil consequences. After recovery from any of the acute febrile affections amenable to salvarsan treatment, when there is nearly always some persistence of latent microbism, there should be a pause of from 8 to 14 days before other injections; and further consecutive injections must be small at first for testing purposes, to be gradually increased.

Epithelizing Action of Aminoazobenzoles.—Martinotti, of Modena, sums up results of his experiments as follows: The coloring matters which belong to aminoazotoluol and aminoazobenzol have a more or less strong and perceptible action on epithelia. This action is expressed by epithelial proliferation after the injection of solutions or emulsions of these substances in the cushion of the rabbit's ear, and after application to recent wounds, a difference being visible according to the nature of the excipient (oil, glycerin, water). The maximum results are supplied by the inferior combinations, weakening as we ascend in the scale. The benzol combinations are superior to the toluols. The term scarlet red is vague and applied to members of both classes. The most powerful epithelizer of all is hydrochloride of diaminoazobenzol, while next in order is aniline yellow.

Berliner klinische Wochenschrift.

August 10, 1914.

Peculiar Traumatic Joint Contracture.—Tietze describes a reflex contracture in joints which are held in rigid positions as a result of traumatism. He refers the reader to a paper read by him before the last German Surgical Congress, entitled "Theory of So-called Arthrogenic Contractures." The subject is limited at present to contractures of the hand and fingers, and the author has had many sketches made from photographs through which the positions of the joints can be studied. The patients are not advanced in years and the lesions are comparatively recent, so that the cases under consideration differ widely from the average of clinical material in which joints are involved. There is no destruction of osseous tissue. The joint positions cannot be voluntarily assumed, and one cannot escape the conviction that the muscular contractures are brought about reflexly from the injured joints. They are by no means characteristic, for the same positions occur in spastic paralyses during forced attempts to perform certain movements. In the clawlike attitudes there is a suggestion of the ape, and the author and Foerster have long upheld the view that in spastic paralyses a phylogenetic element is visible which clearly possesses a reflex mechanism. In certain healthy individuals these clawing and climbing movements and attitudes can apparently be executed voluntarily. Foerster has thus far devoted his attention chiefly to the lower extremities, but the author believes the theory is more readily applicable to the upper limbs.

Are Worms (Oxyuris) Directly or Indirectly Responsible for Appendicitis?—Aschoff states that the relative frequency of oxyuris infection of the normal or not acutely inflamed appendix has long been known. The picture of oxyuris pseudo-appendicitis described by the author several years ago has been essentially upheld by the results of Rheindorf's investigations, and its fre-

quency is admitted. The finds depicted by Rheindorf of the formation of fissures in the mucosa of the appendix, attributed by him to the immigration of the oxyuris, are essentially mere artefacts. As long as there is no evidence that the oxyuris can cause gross epithelial defects or tissue destruction which persists for a time, the assertion of Rheindorf that the oxyuris can cause appendicitis indirectly must be regarded as unproven. The part played by the oxyuris in causing pseudo-appendicitis should lead the profession to pay more attention than heretofore to this parasite. Children with attacks suggesting appendicitis should receive thorough treatment for worms, especially as the symptoms often reappear even after removal of the appendix, unless the cause has been removed.

Relation of Atypical Gout to Affections of the Respiratory Organs.—Mayer first mentions the long known relationship between typical gout and asthma and adds that the latter also occurs in atypical gout. His conception of the latter is extremely simple—disturbed purin metabolism without gouty paroxysms. He attacked the problem by testing the purin metabolism of 40 subjects with asthma and chronic bronchitis, the test being again very simple—the injection of uric acid and piperazin into a vein and watching for uric acid retention. This phenomenon he found present in 9 out of the 40 patients, agreeing in all respects with the same finds in typical gout. In nearly all of these there was evidence of metabolic anomalies—gout and diabetes in ascendants and near relatives, children with exudative diathesis. The respiratory complication of atypical gout was always one and the same—a dry bronchitis known since Laennec's time as characteristic of typical gout. Upon this foundation paroxysms of asthma readily develop, for example under the influence of alcohol and food rich in nucleins. Atypical, like typical gout, causes tuberculosis to pursue a mild chronic form—the so-called fibroid phthisis; tuberculosis also tends to cause typical gout to become atypical.

Münchener medizinische Wochenschrift.

July 28, 1914.

Calcium Milk for Sick Nurslings.—Weih states that Finkelstein's albumin milk represents a great advance in the nourishment of sick infants. Later it appeared that this preparation could be replaced by milk mixtures containing an addition of lime salts. A casein calcium was placed on the market under a trademarked name and recommended for milk mixtures in the dosage of twenty grams to half a liter. Still more recently another commercial substance has been advocated which contains double the lime and phosphoric acid content of the first named. It contains 20 per cent. of tricalcium phosphate and albumin representing 10.5 per cent. nitrogen. This is added to ordinary full milk in the proportion of thirty grams to half a liter. The chief indications are rickets and spasmophilia. The older calcium therapy has largely been abandoned, because it has never been proved that rickets is purely a deficiency disease. Recent experiments have, however, shown that the tissues are at fault—the various collagenous structures which are unable to fix the diet calcium. It has been shown that when given with phosphorized cod liver oil calcium is well retained in the body, hence in rickets we must have lime ingestion. In any case acute or florid rickets shows marked waste of both phosphoric acid and lime. It is believed that calcium triphosphate if combined organically with albumin is much better retained than when given alone. In regard to spasmophilia it has now been proved that the brain of a spasmophilic child is poor in lime in comparison with the normal child. The former also suffers from calcium waste. Certain other affections are no doubt traceable to lime deficit—constitutional eczemas and dyspepsias. The treatment is no panacea for the nursling but is held to be indicated in spasmophilia, rickets and acute disorders of nutrition in addition to eczema. Other synergistic measures are advocated.

Erythema Infectiosum.—Heisler states that this condition is quite distinct from scarlatina, measles, rötheln, and the "fourth disease" of Duke. Last spring the author treated a petty epidemic of 25 cases. As a rule there are no prodromes. A maculopapular efflorescence appears on the cheeks and becomes confluent, giving the face a swollen look, and a feel of induration. The color of the rash is bluish-red. The spread is along the extensor surfaces of the arms, neck and shoulderblades, but the rash becomes finer and without tendency to confluence. In two or three days large crops appear on the buttocks and external aspects of the thighs. The first outbreak may have been so fugacious that this location is the first to be noted. Again one rash may quickly vanish and be replaced by another. The victims were of any age up to 16 years, and the incubation period varied from 5 to 14 days. Contagion was very evident, but this is not of a high degree. The only forerunner, seen in some of the cases, was enlarged lymphnodes, at the angle of the jaw, back of the neck, etc. These were as large as almonds, sensitive and firm to touch. Fever was almost always present, seldom exceeding 37.8° C. In a few cases only there was an efflorescence in the mouth, chiefly on the hard palate.

The Cuti-Reaction in Pregnancy.—L. Verney calls attention to this reaction which was first described by Esch of Marburg two years ago. An extract of placenta when rubbed into the skin of a pregnant woman gives rise to a reaction which is similar to that obtained in the von Pirquet test for tuberculosis.—*La Clinica Ostetrica.*

Ligneous Phlegmon of Réclus and Ligneous Thyroiditis of Riedel.—Umberto Cavalli reports one case of each of these conditions. He concludes that in both instances the anatomy is identical, although the seat of disease may be different. The morbid agent is the diplococcus of Fränkel. The treatment should be conservative and should consist in simple incision and drainage.—*La Riforma Medica.*

The Medical College Library.—C. Frankenberger points out that the greatest advantage of such a library is that it places about the student an environment which has a tendency to inspire in him a desire to read and become acquainted with the literature of his profession so freely available. It gives the student the opportunity to keep in touch with the literature in the more important current medical periodicals, and to become acquainted with the recent books and monographs on special subjects. If there is only time to look hastily through them and to become sufficiently familiar with them to know that such a work has been written on that particular subject, it will be valuable knowledge that will prove helpful at some future time. To cultivate in the student the habit of reading in the odd moments and spare time of his medical course is to be encouraged and fostered in every way, for the possession of such a habit after entering in practice will be of estimable value to him. It is safe to say that many who do not acquire this habit during their college career never attain it after graduation. The great difficulty in endeavoring to encourage the acquiring of this habit by the student is the very limited spare time allowed in the already crowded curriculum.—*Journal of the American Medical Association.*

Insurance Medicine.

Medical Section of the American Life Convention.—The fourth annual meeting of this society will be held in Dallas, Texas, on Wednesday, October 7, under the presidency of Dr. James H. Stowell, The following papers will be read: "The Medico-Actuarial Investigation and Its Effects Upon the Selection of Risks," by H. A. Baker, M.D., medical director Pittsburgh Life & Trust Company; "The Influence of Heredity Upon Life Insurance Risks," by William F. Milroy, M.D., medical director the Bankers' Reserve Life Company, Omaha, Neb.; "The Heart in Life Insurance," by J. S. Lankford, M.D., medical director San Antonio Life Insurance Company, San Antonio, Texas; "Certain Aspects of Life Underwriting," by Mr. Franklin B. Mead, secretary and actuary the Lincoln National Life Insurance Company, Fort Wayne, Ind.; "Surgery and Life Insurance," by Marion Souchon, M.D., medical director Pan-American Life Insurance Company, New Orleans, La.; "Inspection of Risks," by E. J. Spratling, M.D., medical director the Empire Life Insurance Company, Atlanta, Ga.; "Some Observations in Physical Diagnosis in the Light of Recent Clinical Research," by E. W. Stevenson, M.D., medical director Standard Life Insurance Company of America, Pittsburgh, Pa. The secretary of the section is Dr. F. L. B. Jenney of Chicago.

Arteriosclerotic and Constitutional Psychic Anomalies.—Reckzeh deals with the estimation of these affections from the viewpoint of the medical insurance examiner and medical jurist. When a subject of late middle age previously free from symptoms begins to complain of vertigo, headache, failing memory, depression or irritability, insomnia or somnolence, diminished tolerance to alcohol, lowering of ethical standards, egoism—in other words a commingling of purely nervous and psychic disturbances—we have good reason to suspect cerebral arteriosclerosis. Analyzed these symptoms are due partly to deficiency, partly to irritation. At times we see speech defects—slow, difficult enunciation with participation of facial muscles; sluggish pupils; differences in the innervation of the facialis, heightened reflexes, spasms, paresthesiæ, and pains. At best, however, it is difficult to exclude here conditions purely nervous. Paresis may be simulated now and then if the mental state is sufficiently compromised. If to simple arteriosclerosis are added small areas of hemorrhage and softening we see vomiting, syncope, mental confusion, and various focal manifestations.

The symptoms may be transitory, and are of a character to be explained by the rigidity of the vessels and insufficient passage of arterial blood; here belong vertigo, confusion, and various speech disorders (also affections of the handwriting). A vasomotor element is no doubt present, to account for the transitoriness of the syndrome. When sleep disorders appear they are likely to persist, insomnia being the rule and somnolence the exception. There may be a long interval between the initial and the later severe symptoms, because compensatory activities may be present. In failing compensation, Reckzeh says, we very soon begin to notice rapid exhaustibility, persistent vertigo, amnesia, alcohol intolerance, and purely mental defects.

This affection, contrary to the customary belief, is no more inclined to attack the educated than the illiterate. Psychic shock may precipitate it. The possibility of syphilis must be borne in mind. The various psychoneuroses must be excluded. Sclerosis of the palpable arteries has some value in differential diagnosis.

Psychic anomalies may be so marked as to involve the question of responsibility and the subject of diminished earning capacity also claims attention. The response to treatment is of some importance, as these may improve under institutional care.

Advanced cerebral arteriosclerosis naturally rejects an applicant outright for life insurance. Beginning arteriosclerosis, on the other hand, if detected at an early period, simply adds hazard to the risk. The diagnosis should not be made until radiograms and the blood pressure have been taken.

The estimation of the constitutional psychopath involves the question of the insurability and responsibility of the born neurasthenic, the hypochondriac, the dysharmonic, the affect personality, the obsessive, the phobic, etc. Naturally no sharp lines can be drawn between the varied expressions of psychopathy. The latter may be manifested by swindling, lying, and criminality of the instinctive type, sexual aberrations, etc. In such cases responsibility must be fixed. In life insurance the tendency of psychopathy to suicide must be borne in mind; also the tendency to addictions. In health insurance the psychopath is somewhat predisposed to disabilities. Unless a psychosis is actually present, the psychopath is held responsible for infractions of the law. "Psychosis" includes imbecility.—*Zeitschrift für Versicherungsmedizin*, 1914, VII, July, p. 193.

Overweights as Surgical Risks.—Individuals of overweight are not good surgical risks, especially those with acute infectious processes. This is perhaps best demonstrated in gallstone disease. Dr. William J. Mayo says that of all the cases of gallstone disease operated on in the Mayo clinic, age for age, the patients average heavier weight than do the average patients with other diseases. It is known that gallstones are more common in women, and in women who have borne children. Aschoff shows that cholesterin, which is commonly a constituent of gallstones, is about four times as common in the pregnant woman as in a man. The particular type of overweight that goes with the consumption of alcoholic beverages is an especially bad risk from the standpoint of surgical operative work.—American Life Convention, March, 1914.

Habits of the Overweight.—The subject of food as well as drink with reference to the habits of overweights is all-important. Millman shows that many of these men live freely and are large eaters and should be restricted in that line. After they pass forty-five they should moderate their appetite and avoid all sugars, starch, and fats, just as they would alcohol. He thinks excessive eating of these forms of food makes a great difference in the longevity of these men. A good rule is to write and ask how many pounds the applicant has gained in the past five years and find out his mode of living. A man who is overweight should take considerable exercise. If these principles could be carried out, Millman says, there can be no doubt that many of these overweights would live longer than they do.—American Life Convention, March, 1914.

Book Reviews.

COLLECTED PAPERS BY THE STAFF OF ST. MARY'S HOSPITAL (MAYO CLINIC) FOR 1913. Octavo of 819 pages with 335 illustrations. Price, cloth, $5.50 net. Philadelphia and London: W. B. Saunders Company, 1914.

IN this volume we find all the articles published during the year 1913 by W. J. and C. H. Mayo and twenty-six of their associates. A very large range of clinical and experimental work is covered, and probably in no other single volume is recent progress along surgical lines more truly reflected. There are altogether 78 articles, of which 26 are found in the first section, devoted to the Alimentary Canal; 13 in the section on the Urogenital Organs; 15 in that on the Ductless Glands; 11 in that on the Head, Trunk and Extremities; 8 on Technique, and 5 under the caption General Papers. Some of these papers are based upon a very extensive clinical experience, as, for example, 1,800 operations for gastric and duodenal ulcer and gastric cancer within a period of six years, while C. H. Mayo's paper on the surgery of the thyroid is based upon observations of 5,000 operations. Many of the articles not only contain extensive references to the work of other surgeons and investigators in the text, but there is often a considerable bibliography appended for the benefit of those who desire to study the subject more thoroughly.

The illustrations are, as usual, models of perfection, the presswork of the highest class, and it is almost impossible to find an error, typographical or otherwise, that has escaped the watchful eye of the editor, Mrs. M. H. Mellish. It is almost needless to say that this book is practically indispensable to the surgeon who would keep abreast of the times and to those who appreciate the magnificent work that is being done in the field of surgery and its allied branches in our own country.

CHEMICAL PATHOLOGY. Being a discussion of General Pathology from the Standpoint of the Chemical Processes Involved. By H. GIDEON WELLS, Ph.D., M.D., Professor of Pathology in the University of Chicago and in Rush Medical College, Chicago; Director of the Otho S. A. Sprague Memorial Institute. Second Edition, thoroughly revised. Price, cloth, $3.25. Philadelphia and London: W. B. Saunders Company, 1914.

IN the seven years which have elapsed since the appearance of the first edition of this work, much has been done in the investigation of the more strictly pathological aspect of biological chemistry. Numerous studies have been made on the metabolism of the diseases in which the chemical aspect is important, such as diabetes and gout, and a large body of pure chemists have contributed to the investigation of the structure and chemical relationships of the special end products of metabolism. But in spite of all this research the subject is not yet in a form sufficiently co-ordinated so that it can be presented as a systematic whole. There are still great gaps in our knowledge, for example, of the process of the metabolism of uric acid, and even as to the nature of diabetes and the intermediary metabolism of sugar. During the period mentioned there has also sprung up a considerable knowledge on a subject almost untouched before, that is, colloid chemistry; and many of the well-known humoral reactions of the body, such as those between toxin and antitoxin are now considered not to be purely chemical, but to be of a colloidal nature. While the specialist has access to the large German handbooks which have appeared in recent years on the subject of biological and colloid chemistry, the average worker must be content to consult a review such as this work under consideration and to gain from it his knowledge of the subject. It is not unnatural that those subjects which the writer has made peculiarly his own by original investigations are somewhat emphasized, but still a careful examination shows that little has been omitted.

The structure and nature of the more elementary constituents of the cells occupy the first three chapters; then comes the chemistry of bacteria and animal parasites; the special toxins of snakes and poisonous insects, and the chemistry of the immunity reactions; after that the chemical changes which are known to occur in inflammation, in diseases of the circulation, in necroses, in degenerations, and in tumors are discussed; and, finally, the various diseases in which the metabolic aspect is dominant are taken up. The last chapter on the chemistry of diabetes has been written by Dr. R. T. Woodyatt, whose contributions on the subject are well known.

Many changes from the first edition are to be noticed; the work has grown considerably in size; and the references have been brought up to date. The reviewer has noticed very few slips or misprints and the work again takes its place in its revised form as the best presentation of pathological chemistry in the English language.

ISOLATION HOSPITALS. By H. FRANKLIN PARSONS, M.D. (Lond.), D.P.H. (Camb.), formerly First Assistant Medical Officer of the Local Government Board. Cambridge Public Health Series, Under the Editorship of G. S. GRAHAM-SMITH, M.D., University Lecturer in Hygiene and Secretary to the Sub-Syndicate for Tropical Medicine, and J. E. PURVIS, M.A., University Lecturer in Chemistry and Physics in their Application to Hygiene and Preventive Medicine, and Secretary to the State Medicine Syndicate. Price, 12 6. Cambridge: At the University Press, 1914.

THE subject of isolation hospitals comprises many problems in hospital administration and preventive medicine, all of which are admirably presented in this volume. The author, who died just as the proofs of his book were being passed through the press, had produced a work that cannot fail to be of distinct service to all who are interested in the establishment and management of hospitals for infectious diseases. The contents of this volume includes chapters on the following subjects: The history of isolation hospitals, utility of isolation hospitals; substitutes for hospital isolation; areas to be served by an isolation hospital, and combined areas; sites for isolation hospitals; design of isolation hospitals; details of hospital ward-blocks; movable hospitals and hospitals of more or less perishable construction; smallpox hospitals; port sanitary hospitals; removal of patients to hospital; measures for the prevention of cross-infection, "bed isolation," open air treatment; discharge of patients from hospital; staff required for an isolation hospital; infectious disease and the poor law; hospital system of the Metropolitan asylums board; cost of isolation hospitals; sanatoria for tuberculosis, and examples of isolation hospitals. One of the most interesting chapters is that which deals with the measures for the prevention of cross-infection. It is pointed out that the "cubicle" system of bed isolation is the one best adapted for the prevention of cross-infection. In hospitals constructed on the pavilion plan in which cases of the same infectious disease are treated in the same ward, it is necessary to maintain a distance of not less than twelve feet between each bed in order to minimize the chances of contact and of droplet infection from one patient to another. Even with this provision the isolation is not ideal, for, as the author points out, "there is reason to believe that in infectious diseases the primary infection is liable to have accompanying or supervening upon it other secondary septic infections, to which latter the severity of the resulting illness and the occurrence of complications are largely due; that these secondary infections may be different even where the primary infection is the same; and that therefore every patient suffering from an acute infectious disease should be regarded as requiring to be isolated—more or less completely according to the nature and stage of the disease—not only from healthy susceptible persons, and from persons suffering from illness due to other infections, but also from other cases which are classified as being of the same infectious disease." The "block" or "cubicle" system is the one to which considerable attention is being paid at the present day. There are three different systems varying in the degree of aerial separation between the compartments: (1) Each compartment is completely separated from any other and is separately entered from the open air under a veranda, as at the Walthamstow Hospital, England. (2) Each compartment is separated from any other by a partition reaching to the ceiling, but the compartments are all entered from one corridor, as in the Pasteur Hospital, Paris. (3) The compartments are all entered from one corridor and are separated from one another only by partitions not reaching to the ceiling. These partially separated cubicles are unsuited for the treatment of smallpox and chickenpox and of measles during the acute stage of the illness, and there is some risk in the case of septic scarlet fever, but scarlet fever not of a septic type, diphtheria, measles in the posteruptive stage, whooping-cough, mumps, influenza, typhoid fever, and probably typhus can be treated in such a cubicle without much risk to other patients in the ward.

THE MENTAL HEALTH OF THE SCHOOL CHILD. The Psycho-Educational Clinic in Relation to Child Welfare. Contributions to a New Science of Orthophrenics and Orthosomatics. By J. E. WALLACE WALLIN, Ph.D., Professor of Clinical Psychology and Director of Psycho-Educational Clinic, School of Education, University of Pittsburgh, Director-Elect of Psycho-Educational Clinic, St. Louis Public Schools. Price, $2.00. New Haven: Yale University Press; London: Humphrey Milford, Oxford University Press, 1914.

THE keynote of this book is the emphasis which it places upon what the author designates as "orthosomatics," or "the process through which malfunctioning physical organs may be made to function aright," and "orthophrenics," or the "process, mental or physical, of righting any malfunctioning mental power so that the mind may realize its highest development possibilities." The work deals largely with the physical and mental welfare of school children and comprises with some amplification a series of papers which have appeared in various journals, including the MEDICAL RECORD. One of the most interesting chapters is that which discusses the new clinical psychology, in which it is pointed out that in dealing with the development of a child one must regard it as having six ages: a chronological, a physiological, an anatomical, a socio-industrial, a pedagogical, and a psychological. The cases with which the clinical psychologist is concerned are grouped into two classes, those in which the mental variations are fundamental or primary, and those in which the physical deviations are fundamental or primary. The former class includes the feeble-minded children, the "retardates," of which there are estimated to be 6,000,000 in the schools of the United States; the speech-defectives; and the incipient psychotics. The author presents a critical analysis of the value of the Binet-Simon scale of graded tests, and discusses a number of current misconceptions in regard to the functions of this method of determining the psychological age of the defective child. Psychological examination demands more than mere stereotyped testing. "There is no royal road to psychological diagnosis." The Binet tests are not infallible, but an experience comprising a large number of cases leads the author to conclude that the tests "provide a fairly impersonal and uniform method by which to grade or classify, with a fair degree of accuracy, institutional or school cases relatively to one another." Among important chapters in this book are those dealing with individual and group efficiency, with the effects of dental treatment on mental efficiency, efficiency in school organization and the conservation of the mental health of children, and public school provisions for mentally unsound children. The author has written a convincing brief in favor of the scientific study and the specialized educational management of the defective child.

MATERIA MEDICA FOR NURSES. By A. S. BLUMGARTEN, M.D., Instructor in Materia Medica at the German Hospital Training School for Nurses, New York. Price, $2.50. New York: The Macmillan Company, 1914.

THE book is gotten up in excellent style, as regards its paper, printing, and binding. The author has included in the text a wealth of information pertaining to drugs both official and non-official. It is questionable, however, whether the average nurse can digest the material in the form in which it is presented. Of the five examples of prescriptions given, none is written correctly. For instance, the author presents the following as type prescriptions:

℞ Bismuthi Subnitr.....15.0
Mucilago Acaciae.....10.0
Syr. Simplex..... 5.0
Aqua Cinnamomi q.s. ad.....60.0
Misce et. Sig 5j q. i. d.

℞ Extracti Colocynthidis Compositi.....5ss
Rheii .....grs. xxiv
m. et divide in pilulae No. XII.
Sig. one o. n.

Ichthyol (page 60) is spelled "icthyol." It may be a far cry from prescription writing to definitions of mental activity, but one is tempted to quote the following: "Emotion is an act, whereby the brain modifies the action of the body, the consciousness and the motor impulses sent out from the brain." The author has a more intimate knowledge of drugs and of their action than of prescription writing and psychology. These are the only serious shortcomings of this work which may be used by the nurse for quick and usually accurate reference. The numerous tables scattered throughout the book are particularly useful. Of special value to the nurse are the rules for making up solutions of different strengths from stock solutions of known strengths.

TEXT-BOOK OF ANATOMY AND PHYSIOLOGY FOR TRAINING SCHOOLS AND OTHER EDUCATIONAL INSTITUTIONS. By ELIZABETH R. BUNDY, M.D., Member of the Medical Staff of the Women's Hospital of Philadelphia; Gynecologist, New Jersey Training School, Vineland; formerly Adjunct Professor of Anatomy and Demonstrator of Anatomy in the Woman's Medical College of Pennsylvania; formerly Superintendent of Connecticut Training School for Nurses, New Haven, etc. Third edition, revised and enlarged. With a glossary and 233 illustrations, 43 of which are printed in colors. Price, $1.75. Philadelphia: P. Blakiston's Son & Co.

THE third edition of this work is no longer a "text-book of Anatomy and Physiology for *Nurses*," but is frankly stated to be a "text-book of Anatomy and Physiology for *Training Schools and other Educational Institutions*." For some time past there has been a tendency on the part of writers of books for nurses to go beyond the requirements of that class and to cater to the supposed needs of social workers, "research" workers, and others. The volume is much the same as its predecessors, and there are still some slips to be corrected in future editions. Thus, we read that there are four bones in each ear called ossicles; that the pancreas is a ductless gland; that the pectoralis minor has its origin from the three upper ribs. On page 241 we are told that "Internal respiration will be studied under Metabolism," but we have not been able to find it, even with the aid of the index. There is no reference in the index to Proteids, Fats, Carbohydrates, Starches, Sugars.

DIE LEHRE VON DEN OKKULTEN BLUTUNGEN. Von Prof. Dr. T. BOAS. Leipzig: Verlag von Thieme, 1914.

IN this excellent monograph Boas gives a minute description of his important discovery of occult bleeding. The great clinician first describes in detail the best methods of procedure, and the precautions necessary for the detection of blood in gastric contents and feces, and then broaches the subject of the eminent diagnostic importance of this sign in various diseases. In gastric and duodenal ulcers occult blood is found as long as the ulcer has not cicatrized. After a dietetic cure the occult blood disappears. In cancer of the stomach and intestine occult blood is constantly found in the feces and does not disappear after prolonged dietary régimes. The absence of this sign speaks against a malignant disease of the gastrointestinal tract. Boas also lays great stress on the importance of occult hemorrhages for treatment. Whenever this sign is present the indication for the checking of the hemorrhage is given. The treatment will consist in remedies directed against the cause of the bleeding. If it is a mere ulcer a milk régime and rest abed are sufficient. In case it be due to a cancerous affection its radical removal must be aimed at. The little book is a valuable addition to medical literature.

ON DREAMS. By Prof. Dr. SIGM. FREUD. Only authorized English translation by M. D. EDER, from the Second German Edition. With an introduction by M. LESLIE MACKENZIE, M.A., M.D., LL.D., Medical Member of the Local Government Board for Scotland; Late Ferguson Scholar in Philosophy; Late Examiner in Mental Philosophy, University of Aberdeen. Price, $1.00. New York: Rebman Company, 1914.

FREUD'S ideas regarding dreams and their interpretation are even yet but dimly understood by a large number of educated persons in and out of the medical profession, although an understanding of them is absolutely necessary to a full comprehension of the modern theories of the part the unconscious plays in the mental life. In this little book Freud sets forth very clearly, if not convincingly, his theory of condensation and displacement in dream work and his psychoanalytic method of explanation of the dream phantasy. The book will be as interesting to the layman as to the physician, and will be instructive to those who seek to be informed as well as supplying the non-believer with much material upon which to base an intelligent criticism.

Society Reports.

AMERICAN PEDIATRIC SOCIETY.

Twenty-sixth Annual Meeting, Held in Stockbridge, Mass., May 26, 27, and 28, 1914.

(*Continued from page 485.*)

THE PRESIDENT, DR. SAMUEL MCC. HAMILL OF PHILADELPHIA, IN THE CHAIR.

The Caloric Value of the Diets of Sick Infants.—Dr. J. C. GITTINGS read this paper, in which he compared the caloric value of the diets in 125 cases with two standards: (1) The caloric needs based upon the admission weight. (2) The caloric needs of an infant of the same age but of normal weight. The caloric needs were calculated on the basis of the following allowances: 50 calories per pound of body weight during the first three months, 45 calories per pound of body weight during the second three months, 40 calories per pound of body weight during the remainder of infancy (up to two years). The cases were divided into the following classes: Atrophy cases, acute gastrointestinal cases, and miscellaneous cases, including pneumonia, bronchitis, typhoid fever, etc. The results corroborated the general impression that cases of acute gastrointestinal disease with fever, vomiting, or diarrhea received a diet more or less markedly deficient in caloric value, and that gain in weight, on the average, went hand in hand with the administration of adequate nutriment. The value of a conclusion based upon general averages could not always be applied to the individual case, and the danger of allowing theoretical consideration to outweigh careful clinical deductions must be emphasized. The estimation of caloric values of diets must not be considered as a compulsory dietetic indication, and due regard must be paid to the effects of diet upon digestion. On the other hand, it was undoubtedly true that marked caloric deficiency or excess, if persisted in, was reasonably sure to be followed by nutritive or digestive disturbances. The caloric value of the diet furnished at once the measure by which we could estimate the risk of starvation and weigh it in the balance against the risk of increasing indigestion.

DR. CHARLES HUNTER DUNN of Boston said that he had always felt from his clinical observations the fallacy of the minimum caloric requirement. They had tabulated the caloric diets of the infants in their wards and the results differed from those of Dr. Gittings in that the extremes were so great that no conclusion could be drawn from any system of averages that could be of value. Where the extremes were so wide the averages might be false for every individual baby. Some infants made no gain on the lower caloric values and gained when the calories were increased, and in others the minimum number of calories had to be doubled before the infants began to show a gain. The problem was complicated by individual differences in nutrition and in digestive power so that conclusions were not of value as a guide even in the average case.

DR. HENRY DWIGHT CHAPIN of New York said he was glad Dr. Dunn had made a protest. The value of the caloric method of feeding infants had been overestimated. It was the assimilation and nutrition and not the heat production that was of value. It must be remembered that the different food elements must be in proper proportion and that they were not interchangeable.

DR. CHARLES GILMORE KERLEY of New York said that wishing to test the accuracy of the estimated caloric requirements in growing children he had made observations on children and found that some children required considerably more than the estimated standard. It also seemed true in older children that the number of calories required depended on the activity of the child.

DR. FRITZ B. TALBOT of Boston said that in estimating the body surface he had started by getting shadow photographs and had calculated the surface from the perimeter. These children were observed when they were not doing any work unless the question of digestion was considered and that added about three per cent. to the minimum. In answer to Dr. Jacobi's question, one chart showed babies of the same weight and length, but of different ages, but all under weight. The eight and one-half months' baby was naturally thinner than the four months' old baby of the same weight and the heat requirement was greater in the older children in all instances, though the weight and body surface was the same. As had been observed clinically babies under weight were apt to be muscular because they cried a great deal and as they were more muscular more heat was required to maintain the body heat.

The Feeding of Mal-Nourished Infants with High Proteins and Carbohydrates and Very Low Fat Values.—Dr. D. J. MILTON MILLER of Atlantic City made this report, which he said was the result of slow convictions and clinical experience and dealt with no theories of malnutrition. The most successful method of nourishing these children was by human breast milk and too much time was wasted in seeking substitutes before wet nursing was resorted to. Buttermilk, *Eiweisse milch*, and Keller's malt food were applicable for a short period only. The low fat and high proteid and carbohydrate content was characteristic of all these preparations. Many infants having an intolerance for cow's milk became accustomed to it by beginning with very minute quantities and gradually increasing the amount. No infant should be kept long on a fat free diet and when the fat was reduced to minute proportions the carbohydrates should be increased. In their cases the percentage of proteids was never excessive. He had never been impressed by the injurious effects of sugar for if acidosis was produced it was not serious and might easily be corrected. Skimmed milk formed the basis of the formulæ used with one to one and three-quarters per cent. fat. Floured dextrine or dextromaltose was added. The children were not long kept on a fat free diet, though the percentage of fat might always be below that of the normal formula. Eleven children were fed on this principle with very favorable results.

The Good Result of Low Fats and High Proteids in Cases of Artificial Feeding in Infants.—Dr. PERCIVAL J. EATON and EDWARD B. WOODS of Pittsburgh, Pa., presented this communication, which was based on a small series of cases admitted to the Children Hospital in Pittsburgh and were typical of the feeding cases in infants whose heredity was not of the best and whose home environment was bad. Certified milk and gravity cream alone were used. The formulæ were all low in fats; the percentages did not exceed 2.5, and started generally considerably below this figure. The author emphasized the points made in a previous paper on the same subject. The most important being that babies fed according to this general plan, even in hospital work, were less inclined to be ill and had a more stable life as well as a very consistent growth. The formulæ should be adapted in quantity and quality as closely as possible to the individual infant, that is, the balance between the fat and proteid should be maintained for the given infant. These formulæ and practically all that they used nowadays were home modified mixtures, which Bowditch and Bosworth had shown to be more nearly correct than were laboratory mixtures, at least as a rule. Dr. Eaton called attention to a printed form which was filled out each time a new formula was prescribed. It was so simple and complete that any mother or nurse could carry out its directions.

DR. JOHN LOVETT MORSE of Boston said that these papers as well as all others speaking of a "method" in infant feeding were a distinct step backward; they had passed that period. Series of cases could be produced showing the good results of low fat and high proteids and others could be shown proving the beneficial effects of high fats and low proteids; series of cases could be brought forward to prove the value of a low percentage of sugar and others equally convincing could be exhibited which showed the advantages of high percentages of sugar. It was only by a study of the history, the symptoms, the examination of the stools, etc., that one could formulate a plan to meet the needs of the individual baby.

DR. ABRAHAM JACOBI of New York said he would like to disagree with the last remarks. Rules were not made for the individual, but for the general population. There was such a thing as an average health standard, and it was possible to be guided by the rule. Not every case had to be fed from the individual standpoint from the beginning; the general rule might be applied at first and when the individual baby did not develop properly under the general rule the physician might then show his shrewdness in meeting the special requirements of the individual. The remarks in the paper were correct and it was a question if they would have had to be repeated if the papers that had been written were read and then perhaps the new ones need not have been written.

Dr. Henry Dwight Chapin of New York said that the pendulum had swung too far the other way and they were going too far in the low feeding of low fat percentages. The children in institutions did not digest fats well and the remedy for this was fresh air. The children needed individual care and fresh air to assist in the oxidation of fats. It was to be feared that the feeding of low fat mixtures would be productive of a crop of rickets. The normal mother's milk was not low in fats and furthermore the proportion of the different food elements must not be interfered with. As long as they insisted on feeding large quantities of milk sugar they would see diarrhea and burning stools; there was plenty of milk sugar in all milk.

Dr. J. H. Mason Knox of Baltimore said he seldom saw intoxications that could not be attributed to sugar, nor was there much starch intolerance and there was not much starch in the stools. The treatment consisted in giving cereals and gradually increasing the quantity of scalded diluted skimmed milk and then gradually going on to whole milk.

Dr. Roger H. Dennett of New York said that when one could not decide from the history what was at fault one was apt to begin with a high proteid and low fat formula as described in the papers, until there was evidence that a change was needed, when one must select what seemed most applicable. Speaking of a method was certainly a distinct step backward. One might recognize every method as a measure to be used in certain individuals while waiting for finer methods of diagnosis so as to gain by the earlier selection of the most suitable diet for the individual.

Dr. Isaac A. Abt of Chicago said that he agreed that there was no method of infant feeding and that each individual was to be considered by himself. The baby must be considered from the standpoint of his tolerance for the food and as to how much it could do in the upbuilding of the baby, and also how much injury it could do. All progress must be made in learning how to meet the needs of the individual baby.

Dr. D. J. Milton Miller of Atlantic City said that he had never seen any but temporary injury from high percentages of sugar, and that acid burning stools could be rectified by cutting down the sugar, and they might occur when the child was on any one of the sugars. The ideas expressed in the paper were not designated a method, for he did not believe in a method himself, but simply tried to adapt the food to the baby's peculiarities by beginning with a definite percentage of fats and then increasing it according to the indications. The point was to increase the fats as rapidly as possible. Some marasmic babies did well on fats from the first.

Dr. Percival J. Eaton of Pittsburgh said that the children in his series were picked because they were miserable; they were the average babies met with in hospitals. He used the general plan at first and then modified it to suit the individual as he had stated in the paper. The children fed as he had outlined did well in not having bilious attacks or food poisoning. They all did better, however, on a diet containing comparative high percentages of protein and low fats.

Preliminary Report on the Chemical Analysis of Infants' Stools.—Dr. L. Emmett Holt of New York presented this preliminary report based on the analysis of 112 specimens, each being the twenty-four amount and not taking into consideration the number of movements. The observations were made on formed stools, moderately loose stools, and very loose stools. The results showed the output of nitrogen, water, and salts in each. The specimens were taken from the average hospital feeding cases of the better class, the children ranging in age from four to ten months. Charts were presented showing the average percentages of the different substances excreted in each of the above varieties of stools, but definite generalizations were not made.

Dr. Thomas S. Southward said that Dr. Holt's work was exceedingly interesting and he prophesied that if he persevered with it a great deal of good would result from the study of loose stools and formed stools. It might point to some method of bringing the intestinal digestion to such a condition that the intestinal contents would pass more slowly through the intestines. Just how this would be brought about he did not know, but so much depended upon whether the intestinal contents were hurried along without an opportunity for absorption and whether the early digestion split the food into irritant substances, which increased peristalsis and permitted their escape before the proper absorption took place, and he felt sure Dr. Holt's experiments would indicate some way of solving this problem. He asked Dr. Holt whether he had met with the paradoxical condition that children with constipation often lost weight and whether he had a theory to account for this paradoxical condition. One would expect a gain in weight in these cases.

Dr. Fritz B. Talbot of Boston stated that Dr. Holt had said that the carbohydrates did not appear as such in the stools and had not been estimated in his analyses. He had estimated them in a very crude way by titurating the acidity of the stools. He assumed that the sugars were split up into a variety of acids and he had isolated three of these acids and titurated them.

Dr. Charles Gilmore Kerley of New York said that the salts were a factor in the production of tetany and he would like to ask whether the production of diarrhea would relieve the symptoms of tetany.

Dr. L. Emmett Holt of New York said that his paper was only a start, but that he hoped that by following out the work information might be obtained that would be valuable in infant feeding. He said he could not answer Dr. Southworth's question. Constipated stools were almost always alkaline and loose ones acid. In reference to tetany, he believed that it was true that if diarrhea was produced the tetany was relieved. He had induced diarrhea and found that the children lost sodium and chlorine. The elimination of sodium and potassium relieved the nervous irritability.

One Hundred and Forty-one Cases of Recurrent Vomiting in Private Practice.—Dr. Charles Gilmore Kerley of New York presented this paper. He stated that all cases seen in consultation and all those in which there was any question as to the correctness of the diagnosis had been excluded. There were 70 boys and 71 girls. The family histories of these patients showed that there was rheumatism in one or both parents in 40 instances, sick headaches and bilious attacks in 40. The cases of recurrent vomiting occurred in the vast majority of cases in the offspring of those who had not been occupied for two or more generations with manual labor. Of the series 69 gave a history of having been difficult feeders. Recurrent colds were also present in 41 per cent. In 12 there was a definite history of eczema, six had a habit tic, 14 either had now or had had enuresis, and 13 had had rheumatism. The presence of acetone in the later attacks was noted with but very few exceptions. The onset of the vomiting occurred in 37 cases during the first year, in 24 during the second year, and in 21 during the third, while in the others it ranged from the third to the ninth year. In different individuals the duration of the interval between the attacks varied greatly, as did also the severity of the attacks. There was a rise of temperature in 90 per cent., ranging from 100° to 102° F. in the majority of the cases, though a few showed marked rises. In the vast majority of cases the recurrence could be controlled if the continued cooperation of the family could be secured. The association of recurrent vomiting with other forms of illness, such as eczema, spasmodic laryngitis, cyclic vomiting, and recurrent bronchitis and asthma was interesting. While two or more of these conditions were not ordinarily met with simultaneously in the same child, not a few suffered with a number of these conditions in alternation. In every instance the diet was a pronounced factor in influencing the susceptibility of the patient. Cow's milk, butter, and sugar were eliminated from the diet. One egg perhaps was allowed every third day. Saccharine was permitted as a sweetening agent. Three meals daily were allowed but nothing between meals. Red meat was given scantily three times a week. Poultry and fish were given at other times. In some cases skimmed milk was given, but never more than one pint a day. A grave error in our management of many children was the free use of cow's milk, butter, and sugar. The average child would be better off if given not more than one pint of milk daily after the fifteen months. Sugar was not a necessity; unknown millions had lived without it. The further treatment consisted in the internal use of salicylate of sodium or bicarbonate of sodium, independent or in combination as advised by Dr. Rachford. This drug treatment was carried on with rest periods for months or years, as the case might require. Exercise, a hot bath at night, and physical therapeutics also formed part of the treatment. During the acute attack a weak solution of bicarbonate of sodium was best retained in the strength of five grains of bicarbonate to eight

ounces of hot water. This was given freely. As a laxative the magnesium preparations were best retained. When the vomiting continued for from twenty-four to forty-eight hours the patient was given colonic flushings with bicarbonate of sodium, two drams to eight ounces at six or eight hour intervals. Nothing was gained by attempts at forced feeding. While not forgetting that anaphylaxis and reflex neuroses from various abnormalities were still to be considered as operative causes in such affections as asthma, recurrent vomiting, migraine, etc., he emphasized the fact that all were notoriously frequent in the children of gouty and lithemic ancestors.

Dr. Irving M. Snow of Buffalo said his ideas were at variance with those of Dr. Kerley, and cited the case of a child with recurrent vomiting and profuse gastric hemorrhages who made a complete recovery on a diet containing cream, butter, and bacon fat. Gastric analysis showed that the hyperacidity was reduced by this diet together with strong alkalies.

Dr. Charles Hunter Dunn of Boston said that in a similar series of cases seen in private practice and in association with Dr. Rotch he had been interested in the relation of acid intoxication to these cases. There seemed to be two types of cases, those of acid intoxication such as Dr. Kerley had observed, and a class in which large doses of bicarbonate of sodium did not seem to be of the slightest benefit. He had given up the use of bicarbonate of sodium because of the impression made on him by two cases of fatal hemorrhage, and now would not even risk using it by the rectum.

Dr. Alfred Friedlander of Cincinnati said that Martin Fischer and others who used the alkaline treatment in severe cases were now using a solution of dextrose 20 grams and sodium chloride 14 grams to the liter per rectum. The results thus far had been remarkably good; the profound exhaustion frequently present was not seen and the patients rallied more promptly. It was too soon to make definite statements about this treatment, but it ought to go on record because of the excellent results claimed for it.

Dr. Isaac A. Abt of Chicago said that the diet during interval seemed to have no effect on the attacks; they occurred about so often no matter what food was taken. Such things as a nervous attack or a mild infection might bring on the attack. In the treatment of these cases eight per cent. glucose in physiological salt solution had been recommended. He used bicarbonate and ice cold chloroform water, repeated frequently.

Dr. J. P. Crozer Griffith of Philadelphia said that years ago he had come to the conclusion that there were cases of recurrent vomiting that could be benefited by bicarbonate and again there were others that could not be helped by it. In some cases even treatment between the attacks had no effect. In his experience some patients had been helped by a change of diet and others were not helped in this way. He had found nothing as good during the acute attack as a hypodermic of morphine; it might be true that it stopped elimination, but it was also true that it sometimes saved life.

Dr. Henry Heiman of New York said that cyclic vomiting was a metabolic disturbance of fats as well as of proteids and induced the formation of acetone bodies. The acidosis was not fatal, but he had seen a case of eclampsia with a temperature of 108° F. and no treatment could have saved the child. The moderate cases responded to bicarbonate of sodium in peppermint water, which acted as a mild analgesic. One might also use bicarbonate in small amounts by rectum, by hypodermoclysis, or by intravenous injection. Intermittent treatment acted as a prophylactic.

Dr. John Ruhräh of Baltimore said they were confusing several different conditions. The proper management of the diet during the interval between the attacks did do good. If the condition was due to an excess of fats or proteids or carbohydrates, one certainly did some good by cutting out the offending substance. There were attacks due to reflex nervous conditions which recurred and it was difficult to say what was the basis of these.

Dr. Henry L. K. Shaw of Albany emphasized the danger of sudden fatality in some of these cases which seemed to give a favorable prognosis.

Dr. J. H. Mason Knox of Baltimore said that in certain cases in older children where there was hyperacidity atropine pushed to the physiological limit in connection with other measures would be found effective.

Dr. William P. Northrup of New York said that in connection with the favorable report given of the result of physical therapeutics in one discouraging case he wished to emphasize the beneficial effects of physical therapeutics in some of these cases in which other methods of treatment had failed.

Dr. Charles Gilmore Kerley of New York said that he realized that there was such a thing as carbohydrate starvation, but an excess of sugar brought about just as bad results as too little. He had found physical therapeutics a most valuable adjunct in the treatment of recalcitrant cases. These cases were not due to anaphylaxis but rather answered the description of accidents as it was accepted at the present time. He could not see why the diet in the interval would not be of benefit; the great difficulty lay in having it carried out.

Weights and Measurements of Infants and Children.—Dr. Rowland G. Freeman of New York, after pointing out the advantages of having such standards, stated that he had made an average weight chart of 278 children seen in private practice and for purposes of comparison had taken the weights and measurements of 1,000 children in the Roman Catholic Orphan Asylum in New York City. He had selected this institution because it was located advantageously overlooking the Hudson and the children were living under good conditions. He had also compared his series with the Dr. Holt's averages and with those of 69,000 school children. The first chart showed the weight of 120 well cared for children compared with institution children. There was a considerable difference after the first month. The breast fed children showed greater weight throughout the first nine months while the artificially fed kept fairly below. The well-cared-for children were almost all artificially fed after the first month and showed that the American method of feeding children seemed to compare favorably with the methods advocated in Germany. It was evidence of the excellent care given the asylum children that they averaged a quarter to a half-pound heavier than the school children. The asylum children averaged somewhat taller than the school children but were well below the well cared for children. Children that were under good control so far as diet, rest, and exercise were concerned showed a great advantage over the data at command concerning other children both in weight and height during the first twelve years of life, and at the twelfth year they surpassed the average by four pounds in weight and six inches in height.

Dr. Thomas S. Southworth of New York pointed out the importance of differentiating between the babies that were breast fed and those artificially fed at different periods during the first year. The normal breast fed baby grew more rapidly at first but slowed down later, while in the bottle fed infant the reverse was true, it gaining more rapidly during the latter part of the year. The breast fed baby showed a tendency to relax his gain at the age of three or four months when the maternal milk supply became relatively insufficient. At this time attention should be directed to increasing and improving the milk supply of the mother. During the last six months there was a relative insufficiency of breast milk which must be supplemented; it was therefore most important that every child should be carefully supervised during the first year as it was thereby possible to keep him gaining rapidly by adding to the food when there was a tendency to fall below the proper weight. Avoidance of infectious colds during the first year was important, since they might cause the delicate child to stand still in weight.

Dr. Godfrey R. Pisek of New York deplored the lack of statistics in regard to the weight and height of children from the ages of two to five years. He said he had been looking forward to the time when the Society would adopt resolutions requesting each member to contribute a series of measurements of children in his private practice. There should be such a collective investigation by the Society.

Dr. Henry L. K. Shaw of Albany, N. Y., said he agreed with Dr. Pisek and that in New York State under the new law every physician who examined a school child had to fill out a blank showing the weight and measurements he had taken himself. There were more than 98,000 children from which to draw an average. There was also a standard score card issued by the Women's Public Health Committee of the American Medical Association for the better babies' contests. If they did not take the form adopted by the Smithsonian Institution they might use those of the American Medical Association as they provided for full measurements and were easy to correlate.

Dr. Godfrey R. Pisek of New York thought that they could not accept the statistics of New York City as the measurements had been indiscriminately made and the figures they wanted would have to be based on an absolute standard like that of the Smithsonian Institute.

Dr. Rowland G. Freeman of New York said he would like to point out that in regard to the normal weights during the first year the average gain during the first three months was five pounds; during the second three months, three pounds; and during the third three months, two pounds.

Diseases Connected with Meckel's Diverticulum, with Special Reference to Diverticulitis.—Dr. J. P. Crozer Griffith of Philadelphia presented this communication. He stated that the complete history of the case was recorded in the Journal of the American Medical Association for May 23, 1914. The case was reported because the combination of clinical manifestations was so unusual, so unexpected, and so misleading. The patient was a child of nineteen months, who after slight indigestion, began to suffer from increasing anemia, and on one occasion from suppression of urine. There was a history of reddish colored stools which continued together with an increasing anemia and abdominal pain, gradually becoming very severe. There was also tympanites. Rectal and abdominal examination showed nothing abnormal. The final clinical diagnosis was that of secondary hemorrhage depending on hemorrhage somewhere in the intestinal tract. During the attack there had been a moderate irregular febrile reaction. The autopsy revealed what was probably a primary ulcerative inflammation of Meckel's diverticulum, which was the cause of the persistent leaking of blood from the bowel and of the anemia. This inflammation extended to the serous layer of the diverticulum, producing a secondary purulent peritonitis, localized by the matting of the coils of the ileum around the seat of suppuration. The severe abdominal pain was due to this peritonitis, and in part to the kinking of the intestine, making evacuation of the bowels difficult and accounting for the constipation. The nephritis appeared to have little part in the complex symptoms and fatal termination. The author discussed the various lesions of Meckel's diverticulum and gave statistics regarding their frequency, giving special attention to diverticulitis with reference to its causes, symptoms, and diagnosis. It seemed that no case had yet been correctly diagnosed during life.

The Sarah Morris Children's Hospital of Chicago.—Dr. Isaac A. Abt of Chicago gave a lantern-slide exhibition showing the floor plans, and special features of this modern children's hospital.

Anthropometric Methods, with Suggestions for Improvements Based on the Measurements of 540 Infants.—Dr. Henry L. Coit of Newark presented this communication. After calling attention to the lack of data relative to infants and young children and the deficiencies of those that they did have, Dr. Coit exhibited a number of tables showing the results of the measurements and comparisons made in his series of 540 infants. These measurements were very complete, including weights, height, length of limb, trunk, circumference of the head, etc. He had found a considerable difference in the sexes and had made a table of general averages for all infants, one for male, and a third for female infants. There were other factors, such as that of race, social condition, etc., which affected the value of averages and he hoped by further study and comparison to work out standards that would take these factors into consideration.

On the Artificial Cooling of Sick Rooms in Summer: A Preliminary Report.—Dr. Henry Heiman of New York reported the results of an experiment on the artificial cooling of a children's ward for enteritis at Mount Sinai Hospital last summer. He said that the etiology of gastroenteritis was in their opinion dependent on nutritional disturbance having a secondary bacillary basis which accounted for its prevalence during extreme heat. The temperature of the room that was cooled ranged from 63 to 74 degrees and was at all times from five to eleven degrees below that of the outside air. The relative humidity was very much the same as that of the outside air but the absolute humidity was diminished by cooling. Thirteen patients with gastroenteritis were selected and placed in this ward and the treatment given them differed in no way from that of any ordinary case of enteritis. There were comparatively few cases of this disease last summer so there were no cases in the open ward with which to compare these patients. While it was too soon to draw conclusions they had gained the impression that in this ward the children were more comfortable, cried less and looked less sick and parched. They did not wish to belittle other methods but to introduce this suggestion as a help in the treatment of gastroenteritis. This method was not applicable to moribund or premature babies but was suitable in all others.

Dr. Heiman showed lantern slides illustrating the apparatus and method of cooling.

Dr. Henry I. Bowditch of Boston said that there was one pitfall in connection with an apparatus of this kind to which he wished to draw attention. In Boston they had installed a similar plant at a great expense but the fan was a long way from the coil room and in consequence the ducts became clogged with dust and they had given up the use of the apparatus. The plant shown by Dr. Heiman had short ducts as it should have. A series of coils should be placed near the wards rather than a central plant a long way from the ward.

Dr. Fritz B. Talbot of Boston said Dr. Bowditch had forgotten to say that they had attempted to start the apparatus one day and the dust from it had given rise to infectious colds which affected 75 per cent. of the children and all the nurses in the ward.

Dr. B. S. Veeder of St. Louis said that they had a room which was cooled with refrigerating pipes all along one side wall and this cooled the room without the cold air being forced into the room.

Dr. Samuel S. Adams of Washington described a case in a private home in Washington in which he affected a lowering of the temperature of the room by directing a current of air from an electric fan over a large cake of ice, being careful to keep the patient out of the draft. The temperature outside was 90 degrees and by this contrivance the temperature of the room was kept at 75°F. When the temperature was permitted to rise the patient went into coma. It was finally decided to remove the patient to a cooler place and the change for the better in his condition when taken to an elevation in New York State was most striking.

(To be continued.)

Nervous Diseases of Elementary School-Children.—J. Priestley has made a study of the records of 62,236 children medically inspected during 1909 to 1911. The children were of the age groups 5 to 6, 8 to 9, and 12 to 14, one-fifth, approximately, being of the ages 12 to 14 and two-fifths each of the ages 5 to 6 and 8 to 9. There were 31,352 boys and 30,884 girls. There was no overlapping in the groups, *i.e.* no child figures twice over in virtue of having passed from one age period into another. The author found that in only two complaints, viz., chorea and headache, were more cases recorded against girls than against boys; and in chorea the predominance might depend upon the predominance of rheumatism among girls. In functional disorders boys and girls are approximately equal; but in every other nerve complaint, including all the serious ones—mental dullness and defect, stammering, paralysis, epilepsy—there is a marked preponderance among boys. An explanation of this unequal incidence of nervous disorders in boys and girls, as regards mental dullness at least, has been sought in the fact that the brain of girls ceases to grow in weight at about the age of seven, while in the case of boys it continues to grow until puberty. A still growing brain might be supposed to be more liable to derangement than one that has ceased growing. It is not improbable that this physiological difference of growth plays a part in the sex differences as regards nervous affections; but is it the fundamental course of difference? To put this to the proof one ought to contrast boys and girls at age 5 to 6 while the brain is still growing in both. The author was not in a position to do this fully, since children are not classified for dullness or mental deficiency until the are about 8 years old. But it is possible to contrast them in regard to all the other important nervous complaints. Headaches for obvious reasons should be left out of calculation; it is difficult to judge of headaches at the age 5 to 6; but taking all other cases of nervous disorder together, stammering and defective articulation of speech, spasmodic and paralytic affections of childhood, epilepsy, chorea, functional disorders and asthma, one finds that 12,837 boys of 5 to 6 showed 601 cases of disorder, or 468 per 10,000, while 12,437 girls of 5 to 6 showed 431 cases of the same disorders, or 346 per 10,000.—*British Journal of the Diseases of Children.*

Therapeutic Hints.

Intravenous Injections of Chloral in the Treatment of Tetanus.—M. Roch and Mlle. E. Cottin report the case of a boy aged 13 years in whom this method of treatment was successfully employed, in addition to the administration of chloral by the mouth and by the rectum. The patient weighed 23 kilograms and in the course of 20 days received 156 grams of chloral, of which 7 were administered by the mouth, 112 in suppositories or in enemata, and 37 in intravenous injections. The effect of this method of treatment was a remarkable control of all the spasmodic phenomena. As regards the proper solutions of chloral when these are given intravenously, the author states that they should not be of greater concentration than 5 per cent., and should be allowed to flow into the veins very slowly.—*Gazette Médicale de Paris.*

Treatment of Cardiac and Nephritic Ascites.—Goodhart and Still recommend the following as useful diuretics in children:

℞ Tincture of digitalis, ʒj
Solution of acetate of ammonia, ʒjss
Spirit of nitrous ether, ʒij
Syrup of tolu, ʒss
Caraway water, ad ʒiij

M. et Sig. One teaspoonful every two or three hours.

℞ Tincture of digitalis, ʒj
Theocin sodium acetate, gr. xx
Spirit of chloroform, ♏xxx
Glycerine, ʒiij
Peppermint water, ad ʒjv

M. et Sig. Two drams every six hours may be given to a child eight years old.—"Diseases of Children."

The Use of Diuretics in Nephritis.—W. Langdon Brown notes that caffeine, theobromine, theocin sodium acetate, and diuretin act as direct stimulants to the renal epithelium, and for this reason should not be used if this epithelium is damaged. The use of these drugs should be restricted to those cases in which the kidneys are not organically diseased. An exception is made in the case of theocin sodium acetate, which in doses of 2 grains twice a day seems to render the kidney more permeable. Digitalis should be used as a diuretic only in cases in which the heart is failing. A useful diuretic is Basham's mixture which also corrects the secondary anemia.—*Clinical Journal.*

Bier's "Substitution Therapy" in Ophthalmology.—J. Ferrux states that this method of treatment is applicable in cases of external inflammation of infectious origin, in which the local use of antiseptics does not suffice to relieve the intensity of the process. The method consists in the production of counterirritation, the secondary leucocytosis that is evoked in the inflamed area being effective in combatting the infectious process. Schaub has employed this method with success in the treatment of trachoma, and in various other types of chronic ophthalmia.—*Gazzetta Medica di Roma.*

Belladonna in Gastric Ulcer.—E. Müller recommends the following powder in the treatment of the pains of gastric ulcer:

℞ Extract of belladonna, 0.02 gram.
Bismuth subnitrate, 0.2 gram
Calcined magnesia, 0.4 gram

This should be given three times a day.—"Die Therapie des praktischen Arztes."

THE SURGICAL MANAGEMENT OF PERICYSITIS.*

BY EUGENE FULLER, M.D.,

NEW YORK.

To the general practitioner the word cystitis seems fairly satisfactorily to describe an abnormal condition of the bladder. To the genitourinary specialist, the term unaccompanied by some descriptive adjective, conveys little meaning. This, of course, is due to the differential diagnostic studies of inflammatory vesical conditions. Before the day of the cystoscope, much had been learned, and since the general use of that most valuable instrument further great and progressive strides have been made. Still it seems that perhaps the cystoscope may have indirectly led to error, and if so it is a fault confined to those who specialize too narrowly. That error lies in considering all cystites to be phases of intravesical disease; in other words, in basing diagnoses wholly on the visual appearances presented by the cystoscope.

Where the primary focus and source of disease is extravesical, as in most instances of pericystitis, it is natural that the diagnostician who so bases his opinion should be grievously mistaken. The mistake in diagnosis generally means the commencement of serious trouble for the patient, since most cases of pericystitis are greatly aggravated by the palliative and operative treatments found useful and curative in other forms of the affection. While in the female, septic foci connected with the womb and tubes account in most instances for the primary source—the inflammatory processes extending therefrom to and through the bladder wall—in the male the primary source in most instances lies in the seminal vesicles.

In a paper entitled "Operative Cure for a Hitherto Unrelieved Class of Cystites," read before the American Urological Association in 1906 (*Am. Jour. of Urology*, December, 1906), I first called attention to this condition, and remarked as follows: "In the early performance of seminal vesiculotomy, the operation was undertaken for the relief of the usual symptoms, chiefly of a sexual nature, which accompany chronic inflammatory involvement of the seminal vesicles. In the study of the results in these cases, I found incidentally that in a number of them symptoms of cystitis which had coexisted with those of a sexual nature spontaneously disappeared after convalescence from the operation. This fact led me to make a careful cystoscopic study of the bladder in a series of cases of seminal vesiculitis, I found, as a result, that in those of them where the bladder was involved the lesion was confined to the base of the organ, in fact, to that part of the structure lying over the seminal vesicles. In some of them, where the inflammation about the seminal vesicles had been extensive, I found, likewise, that the inflammation invading the base of the bladder had been extensive and had extended further than the underlying portions of the seminal vesicles. In all these cases, the other portions of the bladder were normal, or nearly so, in appearance.

"From these cystoscopic studies, it seemed reasonable to infer that the lesions of the vesical bases accounting for the cystites were really peripheral ones, the center foci for which were the infected seminal vesicles, the germs in the bladders having penetrated the intervening tissues from the cavities of the seminal vesicles. In other words, I classed the bladder inflammations as localized pericystites. In mild cases, the cystoscope showed the vesical mucous membrane of the area involved to be red, infiltrated, and edematous, while in the severe types granulation tissue had in large measure taken the place of the mucous surface. Here and there on these granulations would be pus flocculi, films of inflammatory exudate, and spots of hemorrhage. In some of the advanced cases, the least instrumental contact with the surface granulations was sufficient to provoke a fairly free hemorrhage. On one of them a triple phosphate crustation had formed.

"As a result of these investigations, I felt confident that a cure for this form of pericystitis would follow spontaneously after the operative elimination of the chronic infection in connection with the seminal vesicles. Acting on this conviction, I have cured, through seminal vesiculotomy, a number of these cases, all, in fact, on which I have so far operated."

This article concluded with the clinical report of four cases wherein complicating pericystites had been cured through the elimination of the primary septic foci from the seminal vesicles. Since that time my further experience in this direction has been extensive and wholly in confirmation of the conclusions expressed in the first article, just quoted. Whereas in those early reported cases the pericystites were, as is usual, localized and confined to the bladder floor lying directly over the seminal vesicles, I have found from my further experience with more aggravated conditions that the secondary vesical lesion need not necessarily be so localized, but that it may extend so as to involve the entire fundus of the bladder, including the lower ureters, and that it can even be pan-vesical, the entire organ being involved. It is this more recent discovery of the pan-vesical pericystitis which may ensue from a very severe grade of infection of the seminal vesicles, which has prompted me to make this contribution.

Before proceeding to the main object of the

*Read June 19, 1914, at Philadelphia before the American Urological Association.

paper, which lies in the clinical recitals, the subject of diagnosis will be briefly mentioned, together with the inefficient or baneful effects of the treatments to which these sufferers have so frequently been subjected.

In making a diagnosis, the clinical story should first be considered. In all cases the complaint of frequent urination occurs. Although the frequency is more marked, as a rule, during activity, still sleep is always very much interrupted. Pain is generally associated with urination, to a marked degree. Suprapubic or perineal discomfort usually compels precipitate urination. There may be, and often is, a scalding sensation during the act, while painful—often severe—vesical tenesmus marks its completion. Although the urine may be fairly clear, bacteria in abundance form a usual feature, and with them pus and occasionally blood in varying degrees. Although the flow of urine may be and as a rule is free, still in the severe cases there frequently will be a record of attacks of retention, generally associated with febrile disturbance. Incontinence, or a condition approaching that state, is a feature where the vesical involvement is extensive. If the lower portion of the ureter is involved, the usual evidences of obstruction in that part are present. If the patient be questioned, some of the various symptoms, sexual in character, associated with inflammation of the seminal vesicles, will usually be revealed. Rectal examination shows extensive inflammatory involvement about the seminal vesicles. Oftentimes this surrounding involvement entirely fills the post-prostatic space, extending backward well beyond the reach of the fingertip and forward into the prostatic capsule, soldering, as it were, that gland to the mass of inflammatory exudate. If a catheter be introduced into the bladder after urination, little or no residuum is usually found; and should the bladder be distended its capacity will be shown to be limited in all cases, while in those where the pericystitis is extensive, from two ounces to a drachm only can be forced in. If the attempt then be made to inject more than the indicated capacity, a painful vesical expulsion will be provoked which will force out violently not only all the fluid injected but the catheter as well. Should there be a suspicion that nervous or painful intolerance, rather than limited vesical capacity, might be the accounting factor, sufficient chloroform could be administered to produce primary anesthesia. If the former conditions prevail, it would be found that more fluid could then be injected, whereas the anesthetic state would not in the least alter the vesical capacity when dealing with pericystitis. The intravesical findings revealed by the cystoscope in cases where limited areas of the vesical base are involved have already beeen mentioned. In cases where greater areas are affected, the same appearances are more extended, while in extreme instances of pan-pericystitis the cystoscopic lamp illuminates a cavity the size of an English walnut, or much smaller. Such cavities show surfaces of granulation tissue and deep serrated folds caused by the contracted state of the organ.

Although in the great majority of instances of pericystitis the primary factor is extravesical, still one should always be alive to the fact that the origin of trouble may be intravesical, the inflammatory process having extended through the muscular walls of the bladder, finally reaching and involving the surrounding fibrous structures. This, indeed, appears to be the idea generally accepted by the profession when the question of an accounting cause is raised. It is a well-known fact, however, that the mucous lining of the bladder has, to a marked degree, the quality of resistance to the submucous extension of an inflammatory process. The one inflammatory process which meets the least resistance is tuberculosis, and in vesical tuberculosis pericystitis generally occurs as a late complication, the mucous surface having been previously destroyed. The only other cases illustrative of this form of extension are those wherein the mucous vesical lining has been so destroyed or injured by caustic or highly irritating applications or by traumatisms that it can no longer offer a successful resistance to the progress of an infection. Stone, foreign bodies, neoplasms, and intravesical injury represent traumatic causes. Very frequently, even in this latter class of cases, tuberculosis will be found as a complicating cause, its coexistence being the reason why the crippled mucous wall has made so feeble resistance to the other existing infection.

The prevalent routine treatments for pericystitis have in all instances been ineffectual. While in some cases the ineffectual treatments have been simply negative, oftentimes their results have been actually harmful, and occasionally distressingly so. In most instances the distressing results follow misconceived operations. The ordinary routine treatment is vesical lavage. If very mild nonirritating fluids are used, no ill results follow; while stimulating agents, such as nitrate of silver, and the various astringents, increase discomfort and do harm. Attempts have been made to overcome the vesical contraction, thus increasing the capacity of the organ by the forcible injection of fluid—the object being to stretch the bladder wall, vesical gymnastics, so-called. Such treatment, besides having been found ineffectual is dangerous, since it causes a reflux into the kidney pelves, and oftentimes ascending renal infection. Treatment with the opposite purpose—that of securing bladder rest through the operative drainage of the organ—is still a surgical favorite. It has, however, the strong disadvantage of always leaving the patient far worse than he previously had been. The bladder, being opened and relieved of its function, contracts still further, so that by the time the surgical opening into it has closed its capacity is much diminished, the consequence being that urinary frequency and urgency become greater than before operation, and as pain is provoked by urination, that symptom also—*ipso facto*—becomes more frequent and more distressing. So thoroughly rooted, however, is this surgical fallacy that certain ones who have failed in so operating seem to have learned nothing, but have apparently been led to adopt the motto: "If at first you don't succeed, try, try again." This, I take it, accounts for the cases of pericystitis coming under my observation, wherein there is a history of multiple cystotomies—in one instance, as many as five. The usual story told by the patients being that first a perineal opening had been made, and then—that primary procedure accomplishing nothing—a suprapubic one had been tried. The only reason a patient can usually give for subsequent openings is that they were made in the hope of finding and correcting something intravesical which had previously been overlooked.

The worst and most baneful treatment to which these sufferers are exposed occurs when they are subjected to prostatectomy, on the supposition that

their troubles depend on disease in that quarter. Such prostatectomies rob the individual of a normal organ, besides greatly aggravating and increasing the pericystitis.

The only efficient treatment, and that can be applied to those cases of pericystitis wherein the primary focus of infection is extravesical, lies in the drainage of such foci through extravesical surgical operation, as advocated in my first article, already quoted.

The following clinical recital records the author's method and results in dealing with advanced pericystitis. Three illustrations are given, the first being perhaps the most important, as it represents an instance of pan-pericystitis. The two others, however, should be of clinical interest, as they emphasize the effects of misdirected antecedent surgical procedures.

Case I.—A young man twenty-three years old, admitted to my service at the City Hospital. His complaint was that he could never hold his urine longer than ten or fifteen minutes, while most of the time the vesical tenesmus was so constant as to cause incontinence. Any exertion brought about the incontinent state. The pains associated with the vesical tenesmus were severe and practically ever-present, corresponding with the urinary frequency. They were referred to the urethra and end of the penis—also to the suprapubic, perineal, and rectal regions. The patient strove to keep as quiet as possible, any jar or exertion greatly increasing his discomfort. There was marked emaciation and some temperature, together with a history of chill from time to time, which indicated that periods of exacerbations of temperature were frequent. The urine, though acid, was loaded with bacteria and pus. It also contained sufficient red blood corpuscles to cause a slight discoloration. At times there was blood present in sufficient amount to be very noticeable, and on a few occasions clots had been passed. The odor was offensive.

The patient was very weak, nervous, and despondent. The story was that four years previously gonorrhea had been contracted, before which time he had been well and vigorous. Since then he had never been well; in fact, increasingly worse. The bladder symptoms occurred shortly after the infection and became more intense until the present status developed. These extreme vesical symptoms had been present for a year. During that time, however, there had been such a marked lowering of general physical condition that it seemed probable, should the existing state continue, a fatal termination would be not far distant. The patient had been in numerous hospitals here and abroad. As long as there had remained any vesical capacity the treatment he had received apparently consisted largely of vesical lavage. The patient had a horror of the treatment, as he felt it had done him much harm, especially when nitrate of silver or harsh agents had been employed. During the first two or three years of his illness there had been much priapism as well as other symptoms pointing toward a disturbed condition of the sexual function. At the present time these latter symptoms had either subsided or become masked through the prominence of the symptoms relating to the bladder.

Rectal examination showed the postprostatic space filled with a sclerous exudate which embedded both seminal vesicles and extended backward beyond the reach of the finger. Bimanual palpation, the free hand pressing against the hypogastrium, provoked great tenderness and had to be discontinued until later when chloroform had been administered. Then, such manipulation revealed the bladder as a firm mass, somewhat larger apparently than a billiard ball. A large blunt sound passed into the bladder revealed no urethral lesion. The capacity of the bladder, even while the patient was under chloroform, was hardly more than a drachm. The cystoscope illuminated a small chamber, the walls of which consisted of luxuriant granulations. The question of tuberculosis was raised and investigated, with negative findings. My diagnosis was that the case was one primarily of septic seminal vesiculitis, and that the pericystitis which had involved the entire bladder was the secondary outcome of that extravesical infection.

Although I had little hope of materially benefiting the patient, and so told him, I decided to perform a seminal vesiculotomy to drain the primary focus, and at the same time to extend my dissection well beyond the seminal vesicles so as to drain the entire postprostatic area as fully as possible. This was accordingly done. The operation gave prompt relief in ridding the patient of the painful tenesmus, the result being that the frequent voidance of urine was no longer disturbing. The appetite came back and general conditions began to improve. The patient was discharged from the hospital two months after operation, having gained ten pounds, and with a vesical capacity of two ounces. Now—a year and a half after operation—the patient has a bladder capacity of four ounces, can hold his urine for two hours, and voids without pain or tenesmus. He is twenty pounds heavier than at the time of operation, and is stout and vigorous, so that he works regularly at his trade. His sexual function also is in satisfactory order. The urine, though free from odor, still contains some pus secreted from the intravesical granulations, which appear pale and shrunken. Even though no further increase in the vesical capacity occurs, the operation has been a brilliant success.

Case II.—A man, forty-seven years of age, was sent to me with the expectation that prostatectomy was indicated. Two months previously, during an interval of retention, suprapubic cystotomy had been performed and a suprapubic fistula established.

When first seen, the bladder was contracted and the urine escaping suprapubically was very foul. The clinical history showed that the first gonorrhea had been contracted about twenty-five years previously. Since that time, urethral discharge had been a feature of the case. How many times such discharge had represented fresh infections and how many times relapses in connection with existing lesions was debatable. Questioning revealed the past existence of various sexual symptoms indicative of a disordered state of the seminal vesicles. For a considerable number of years, urinary frequency and urgency had been present. Although, as a rule, it had been an easy matter to start the stream on urination and the following flow had been free, still at times it had been difficult, and on a number of occasions complete or threatened retention had occurred, necessitating the introduction of the catheter. As far as could be learned, the amount of urine drawn off by catheter during retention had not been great. The vesical capacity—owing to the suprapubic opening—could not, of course, be tested. The fact that the patient was only forty-seven years old, together with the further fact that the vesical symptoms complained of had been present for certainly over fifteen years, made it, to my mind, very improbable that prostatic hypertrophy was the diagnostic cause for the trouble.

Rectal exploration showed the entire postprostatic space filled with inflammatory exudate which embedded both seminal vesicles and extended to the prostatic capsule. There was no stricture. The suprapubic opening precluded the use of the cystoscope.

Feeling that the extensive lesion in connection with the seminal vesicles accounted for the patient's condition—the bladder symptoms being due to a resulting pericystitis—a seminal vesiculotomy was performed, associated with peripheral dissection so as to drain the entire postprostatic space as thoroughly as possible. After this operation the suprapubic fistula was allowed to close, and it spontaneously did so by the end of three weeks, when full and natural urination was reestablished. At first the act was frequent, not over an hour's interval elapsing between the voidings. In this case a complete recovery resulted. A year after the operation the patient wrote me that he was in better health than he had been since his first gonorrhea. He held his urine for normal intervals and voided naturally, without any discomfort. He was also in order sexually.

This was not a case like the preceding one, wherein the pericystitis had entended so as to envelop the entire bladder, though from the clinical history and the findings at operation the process must have been fairly extensive.

Case III.—A man, forty-five years of age, came to my hospital service suffering from urinary incontinence associated with painful sensations of vesical tenesmus. There was continuous fever and a history of frequent exacerbations of this condition, which were often accompanied by chills. There was constant pain and tenderness in the right renal region. At times the renal discomfort became so severe as to demand opiates.

The chills and febrile exacerbations were apparently often coexistent with the exacerbations of renal discomfort. The urine was loaded with pus and bacteria. The patient had now been sent to the hospital with the expectation that the right kidney would be removed.

The clinical history was that the man had been generally well and able-bodied until one year before, when following some alcoholic excess, sexual strain, and exposure to weather, retention had suddenly occurred. In this condition he had been taken to a general hospital where a prostatectomy had been promptly performed, on the theory that therein lay the cause for the retention. Much fever followed the operation. That feature, together with the symptoms already detailed, had persisted ever since the prostatectomy, although earlier they had encountered greater systemic resistance than at the present time.

The clinical history previous to the retention was that there had been, years before, several attacks of gonorrhea, a relapsing gleety discharge, and intervals of vesical irritability and urinary frequency. There had also been periods of sexual irritation and excitability. The treatment employed for these symptoms had been the occasional passage of large sounds, vesical lavage, and urethral injections.

Rectal examination showed the entire postprostatic space filled with a firm, inflammatory infiltrate, very tender to pressure. Any attempt to inject fluid into the bladder caused marked pain and a prompt urethral expulsion alongside the catheter. Under chloroform anesthesia, two and a half ounces could be injected and retained, allowing a cystoscopic view to be taken. The interior surface of the bladder was then shown to be granular, edematous, and interspersed by deep folds. In places there were thick adhesions, catharral deposits, and areas of punctate hemorrhage. The case was certainly a complicated one. There were evidently two septic foci, one in connection with the seminal vesicles and one in connection with the right kidney. The kidney infection was apparently the secondary one, due —it seemed to me—chiefly to urethral obstruction resulting from periureteral inflammatory exudate which before involving the lower ureter had caused an extensive pericystitis. There was also, in all probability, an element of direct ascending infection from the bladder. The vesical incontinence resulted more from the prostatic operation than from the pericystitis—it seemed to me—since although there was enough pericystitis to account for great urinary frequency, still there was some bladder capacity and had there remained a vesical sphincter there should have been periods showing temporary control.

On considering treatment, I determined, as a first step, upon a seminal vesiculotomy combined with an extensive incision into the postprostatic tissues so as to accomplish the freest possible drainage. I hoped that this operation would not only relieve the pericystitis, but would also, by removing the periureteral inflammation, restore an unobstructed flow from the right renal pelvis. If the right kidney involvement were not too extensive, I figured a spontaneous cure of the renal lesion would result. If this did not follow, then the proper time had arrived for operation on the kidney.

The result from the seminal vesiculotomy was most satisfactory. The kidney complication spontaneously resolved itself after a few weeks, and with it the last vestiges of sepsis disappeared. The bladder capacity returned, so that by the time the patient left the hospital five ounces could be injected. While lying in bed there was then a fair degree of vesical control, though on moving about there was still incontinence. Physical vigor returned with the elimination of the sepsis. Aside from the incontinence—a sequel to the prostatectomy—the patient's outlook on leaving the hospital was wholly satisfactory.

252 Lexington Avenue.

Osteoperiostitis of the Tubercle of the Tibia.—C. Woodward reports the case of a girl aged 11 years who had complained of pain over the tubercle of the left tibia for six months; as she tired the pain grew worse. There was an obvious swelling over the tubercle and tenderness was especially marked on the inner side. The skiagrams showed the condition described by Schlatter and others.—*Proceedings of the Royal Society of Medicine.*

INSANITY AMONG JEWS.*

By A. A. BRILL, PH.B., M.D.,
NEW YORK,
AND
MORRIS J. KARPAS, M.D.,
NEW YORK.

Ever since modern psychiatry came into existence it has been understood that the Jews have contributed more to insanity than any other race. Indeed, when one consults the works of such eminent observers as Kraepelin,[1] Krafft-Ebing,[2] Weygandt,[3] and others, one finds that they all agree that the Jewish race is disproportionately afflicted with insanity. Krafft-Ebing states: "Statistics have been collected with great care to show the percentage of insanity in various religious sects, and it has been shown that among the Jews and in certain sects the percentage is decidedly higher." Kirchoff[4] maintains that "perhaps the Jews exhibit a comparatively greater predisposition to insanity." According to Kraepelin, "in Germany and likewise in England the Jews are markedly higher predisposed to nervous and mental diseases than the Germans." "The Jewish race," says Weygandt, "seems to show a greater tendency to insanity than any other race." Buschan[5] claims that the Jews contribute from four to six times as much to insanity as non-Jews. However, the opinions expressed by these and many other authors are not fully shared by other investigators. Thus Reiger[6] thinks that there is not sufficient evidence to prove that the Jews contribute to insanity a higher proportion than the non-Jews. Ziehen[7] expresses himself in a similar manner: "The attempt to account in numbers for a larger degree of psychic morbidity as to a certain nationality or race or a special climate have in most cases failed." Sioli[8] states: "All nervous and mental diseases familiar to us occur among all nations of the earth, but we are unable as yet to draw any definite conclusions concerning the frequencies and most manifold appearances of the same." The United States Department of Commerce and Labor[9] asserts that "on the contrary, facts from which deductions can be made point rather to a comparatively smaller amount of insanity among the Jews than among people of several other races."

Sichel's[10] careful investigations, based on the records of the Frankfort Hospital for the Insane, showed that although there were relatively more Jewish inmates than the corresponding percentage of the Jewish population in Frankfort, yet this could only be demonstrated in reference to certain groups of mental disorders. However, the other types revealed a smaller percentage than the non-Jewish population. To quote his figures:

	Jews, %	Non-Jews, %
Dementia præcox	31	31
Manic-depressive insanity	31	5.2
General paralysis	9.5	

He also found that the Jews contribute a very small percentage to the alcoholic psychoses.

Similar deductions have been reached by Kirby,[11] who examined the admissions of the Manhattan State Hospital from October 1, 1907, to September 30, 1908. He says: "The figures for the Jewish race bring out several interesting facts. One notices first of all that the Hebrews are practically

*Read before the N. Y. Neurological Society, April 7, 1914.

free from alcoholic psychoses. The figures 0.32 per cent. (cf. author's statistics) represent a single case which occurred in a series of 182 cases of alcoholic insanity. I must also add that this particular patient, a man, is still under observation, having been over a year in the hospital, and certain features in the development of the psychosis, as well as the course of the disorder, suggest the possibility that the case may, after all, belong to the paranoid dementias. We notice the further interesting fact that the absence of alcoholic insanity in the Hebrew is accompanied by the lowest figure for senile dementia and psychosis with organic diseases. The most noteworthy fact gathered from the second column is that the Hebrew race shows by far the greatest percentage of manic-depressive cases (28.43) and the Jew also stands highest in the psychoneuroses and constitutional inferiorities and in involution melancholia. In dementia præcox, with the exception of the English people (28.57 per cent.), the Hebrews are again foremost (27.47 per cent.). In the undifferentiated depressions they are next to the highest. We thus see that in the large group of the so-called functional psychoses, by which we mean those disorders in which certain endogenous or psychogenetic factors seem most important as upsetting causes, the Jewish people outnumber enormously any race."

Pilcz[12] states that adolescent dementia (dementia præcox) and dementia subsequent to acute psychoses and psychoses depending on hereditary and degenerative bases are more frequent (periodic insanity, 28.8 per cent.; secondary dementia, 33.3 per cent.) among the Jews than non-Jews; he, too, found that alcoholic insanity is very rare among the Jews. Thus he quotes Seckinger as saying that in his six years' service in the Allgemeine Krankenhaus in Vienna, he observed only one case of delirium tremens in a Jew, and that in his experience alcoholism plays no role in the etiology of other forms of insanity among Jews. His statistics of Jewish paretics are 18.75 per cent.

It is also interesting to note the reference of some authors concerning the various types of mental diseases among Jews. Hoppe[13] saw only two Jewish cases out of many hundreds of paretics during his twelve years' service in the Allenberg Hospital. Papoff[14] asserts that syphilis is five times as frequent among Russians as among Jews; that tabes is five time as frequent among Russians as among Jews, and that general paresis is six times as often among Russians as among Jews. Similar observations concerning tabes, and paresis, were made by Kajewnikoff,[15] Minor,[16] and Korsakoff.[17] On the other hand, Baedel[18] found over 21 per cent. of general paresis in Colney Hutch, London, and Hirschl[19] 20 per cent of general paresis among Jews.

Spitzka[20] made a careful survey of the various forms of mental diseases in different races; his results were based on the material from Manhattan State Hospital for the years 1874, 1875, 1876, 1877 and a part of 1878. He only dealt with male patients. The total number of admissions for the years mentioned were 2,997.

His conclusions are as follows: "On the whole the different forms of insanity occur in nearly the same proportion in the Anglo-Saxon, Teutonic, Celtic and Hebrew races; paralytic insanity is most common among the Anglo-Saxons and least common among negroes; melancholia is most common among the Germanic people; the tendency to terminal dementia is greater in the Anglo-Saxon than in the German or Celt; and the forms dependent upon hereditary taint are most common among the Hebrews. With these it is in accord that since termination in dementia and the influence of heredity are the factors which chiefly cause an accumulation of the insane population, that the Hebrew and Anglo-Saxon should have the highest proportions insane of their respective populations."

Many other observers could be quoted, but it is not our object to review here the statistical literature concerning insanity among the Jews. It is worthy of note that most of them were compiled in accordance with the old classification of mental diseases, and besides insanity proper, idiocy, imbecility, neurasthenia, etc., were included. The latter does not enter into the discussion of this paper. Moreover, a great many of these statistics were compiled and interpreted by men without psychiatric training.

From the observations mentioned, one can readily see that the sweeping statement that the Jew is disproportionately afflicted with insanity has not been conclusively demonstrated. In the present state of our knowledge one can say that the Jews, like any other race, contribute a higher quota to certain forms of mental diseases.

With the object of throwing some light on this question, we examined the statistical data of the admissions to the Manhattan State Hospital for four consecutive years, beginning October 1, 1908, and ending September 30, 1912.[21] The total number of admissions was 5710 (2803 men and 2907 women), of which there were 1203 Jews (588 men and 615 women). The Jews thus constitute 21 per cent. of the total admissions.

The following table shows the diagnostic grouping of the patients:

TABLE 1

Psychoses	Men	Women	Total
Manic-depressive insanity (manic)	85	133	218
Manic-depressive insanity (depressed)	8	30	38
Manic-depressive insanity (mixed)	14	33	47
Allied to manic-depressive insanity	42	62	104
Dementia præcox (hebephrenic)	16	21	37
Dementia præcox (katatonic)	19	15	34
Dementia præcox (paranoid)	58	41	99
Dementia præcox (simple)	19	7	26
Allied to dementia præcox	22	33	55
Depression undifferentiated	32	66	98
Depressive hallucinosis	4	0	4
Paranoic condition	16	12	28
General paresis	114	25	139
Psychosis accompanying organic brain disease	15	11	26
Constitutional inferiority	38	40	78
Imbecility	9	8	17
Epileptic psychosis	11	9	20
Senile psychosis	20	26	46
Hysterical psychosis	0	1	1
Involution melancholia	0	2	2
Alcoholic psychoses	8	0	8
Infective-exhaustive psychoses	15	28	43
Toxic-gas poisoning	1	2	3
Morphine and cocaine psychosis	1	0	1
Unclassified	21	10	31
Total	588	615	1203

Table No. 2 shows the percentage of Jewish classified admissions when compared with the non-Jews of the same group.

Judging by the figures of these tables one can plainly see that the predominating psychoses are of the functional type. Thus, the highest percentage is found in the Manic-depressive group, second in order, is the Undifferentiated Depressions, the greatest majority of which probal ly belongs to the Manic-depressive class, and third in order is the Dementia Præcox group. The relatively high percentage of the imbecility and constitutional inferiority groups may be explained by the fact that

these diagnoses are only too often made when a foreign Jew is examined by a physician who is unfamiliar with his language and racial characteristics. Moreover, the total number of imbeciles was only 39, 17 of whom were Jews, and of the 234 constitutionally inferiors there were 78 Jews.

TABLE 11—PERCENTAGE OF ADMISSIONS (HEBREWS) CLASSIFIED UNDER THE VARIOUS PSYCHOSES.

Psychoses	Men	Women
Manic-depressive psychoses	29	32
Allied to manic-depressive	10 0	31.3
Dementia præcox	30 2	24.7
Allied to dementia præcox	23 1	26
General paresis	23 7	16.5
Alcoholic psychoses	2 5	0
Senile psychosis	12 5	11.4
Depression undifferentiated	29 9	37.5
Paranoic condition	23 2	8.8
Organic brain disease	10 9	11.2
Infective-exhaustive psychoses	28.5	20.6
Epileptic psychosis	13 4	14.5
Depressive hallucinosis	16 7	0
Drugs and other toxic psychoses	20	13.3
Constitutional inferiority	38.8	29.4
Imbecility	50	38.1
Involution melancholia	0	11.2
Hysterical psychosis	0	33.67
Unclassified psychoses	15.7	9.6
Number of admissions for four years	2848	2954
Percentage of Hebrews	28.6	20.8

The relatively high percentage of the Infective-Exhaustive groups in men may be partially attributed to the poor hygienic conditions at home and in sweat-shops. It should also be remembered that the number of cases is entirely too low for deductive purposes. It is interesting to note that the general paresis group shows a comparatively high percentage. This condition was also found by Hirschl,[19] Pilcz,[12] Benedikt,[22] Beadle,[18] and others whose material comes from large cities. The Russians, however, found a very low percentage of cases of general paralysis among Jews. The explanation lies in the fact that in Russia the Orthodox Jews are in the majority and owing to their rigid religious tenets and early marriages they lead a pure sexual life. The senile and epileptic insanities and psychoses accompanying organic brain diseases show a relatively low figure and the alcoholic psychoses represent only 2.5 per cent. of the male alcoholics. There were none among the female admissions. This concurs with the results found by other investigators.

If we compare the number of insane Jews to the entire Jewish population and to the corresponding number of non-Jews, the results are still more striking.

In order to correlate our data, we have obtained the official estimate of population for the Boroughs of Manhattan and the Bronx, as given by the New York Board of Health for the years 1909, 1910, 1911, and 1912, and compared the same with the total insane population of the Psychopathic Pavilion of Bellevue Hospital for the corresponding years. It is to be noted that the insane admissions to Bellevue Hospital are drawn from the Boroughs of Manhattan and the Bronx.

POPULATION AS ESTIMATED BY THE HEALTH DEPARTMENT ON THE BASIS OF 1905 AND 1910 CENSUS FIGURES

	Manhattan	Bronx
1909	2,294,520	399,853
1910	2,341,383	439,567
1911	2,389,204	483,224
1912	2,438,001	531,219
Total	9,463,108	1,853,863

By the courtesy of the Federation of Churches we obtained the number of Jews for the two Boroughs mentioned for the year 1910, and by taking the average of the total population for the four years and subtracting the number of Jews we found the following results:

Average total population for one year, 2,829,243.

Jewish population for 1910, 807,801, or about 29 per cent. of the total population.

Non-Jewish population for one year, 2,021,442.

The insane population for four years as taken from the records of Bellevue Hospital is as follows:

Non-Jews	10,766	Average	2,691 per year
Jews	3,062	Average	765.5 per year

The relative percentage of the insane population is .0013 for non-Jews and .0009 for Jews, or about 13 insane for every 10,000 non-Jews and 9 insane for every 10,000 Jews, or 1 to 751 non-Jews and 1 to 1053 Jews. In this connection it will be interesting to compare these figures with the statistics taken from Die Sozialen Verhältnisse der Juden in Russland,[23] a work on the Russian Jew. According to this pamphlet—edited in 1906—there are 5,215,803 Jews in Russia, constituting 4.2 per cent. of the whole Russian population. In 1906 there were 4980 insane Jews (2905 men and 2075 women). The percentage of insane to every 10,000 inhabitants was as follows:

Poles	8.51
Russians	9.54
Jews	9.84
Lithuanians and Letts	13.75
Germans	15.04
Rest of population	9.35

This shows that the Jewish quota of insane is slightly higher than that of the Poles and Russians, and considerably below the Lithuanians, Letts and Germans, especially the latter.

It can be readily seen that these figures show about the same proportion as those given by us. In other words, despite the trials and tribulations that the Jew undergoes in changing his environment, he does not contribute a greater quota to the mental diseases than he does in his native Russia.

In this connection it would be interesting to allude to Dr. Hyde's[24] paper. His material was obtained from the Manhattan State Hospital East from all the admissions beginning December 13, 1871, and ending November 17, 1900. His patients include the male sex only. The total number of admissions was 17,135, out of which 1,722 were Jews, that is making 10.05 per cent. of the entire insane population. Indeed, this investigator's conclusions are in accord with ours.

Another author who discusses insanity among Jews in New York City is Dr. Fishberg;[25] he bases his interpretation on Dr. Hyde's paper, but in doing so he commits several gross errors. In the first place, Hyde's material did not represent the "asylums of New York City" as Dr. Fishberg maintains, but it came from a hospital representing one-half of the insane population of the Metropolitan District. It should be recalled that in Dr. Hyde's time there were two Manhattan State Hospitals—Manhattan State Hospital East and Manhattan State Hospital West—under two separate managements. It was not until 1905 that these two hospitals became amalgamated, Dr. E. C. Dent being the first superintendent of this institution. Indeed, Dr. Hyde stated specifically that his material came only from the male division of Manhattan State Hospital and to quote him—"The notes of this paper are made only on the male Hebrew insane.

inasmuch as the females are committed to Manhattan State Hospital West."

Secondly, the insane of Greater New York are harbored in four institutions: the present Manhattan State Hospital, Long Island State Hospital, Kings Park State Hospital and Central Islip State Hospital, in all representing about 14,000 patients.

In explaining the relative small percentage of Jewish insane as presented by Dr. Hyde, Dr. Fishberg falls again into error when he states that "perhaps the care taken by the Immigration Authorities to exclude defective aliens has some influence." It is a fact that the actual mental examination of aliens at the Government Immigration Station at Ellis Island, N. Y., had not begun until 1905 or 1906. Hence, Dr. Fishberg's interpretation cannot be very well applied to Dr. Hyde's paper.

In brief, after investigating the literature on the subject, we were forced to the conclusion that the prevailing belief that the Jew contributes more to insanity than any other race has never been substantiated by statistical data. With the exception of a few investigators, notably Sichel, Kirby and Pilcz, no real effort was made to settle this question. Our own findings, based on four years' statistics from the largest Jewish city in the world, shows that the Jew is not disproportionately insane. We agree, however, with Pilcz, Sichel and Kirby that the Jewish race contributes a rather high percentage to the so-called functional form of insanity, especially the manic-depressive and dementia præcox groups. In this respect, however, the Jew does not differ from other races; there seems to be a certain selectiveness even in abnormal reactions which shows itself in definite forms of insanity. Why the Jew should show a preference for those particular psychoses will form the thesis for our next investigation.

In conclusion, we wish to express our indebtedness to Drs. William V. Mabon and M. S. Gregory for their courtesy in allowing us to utilize their material.

A RATIONAL DIET FOR TYPHOID FEVER,

WITH A REPORT OF TWO HUNDRED CONSECUTIVE HOSPITAL CASES IN WHICH IT WAS USED.

By EDWARD E. CORNWALL, M.D.,

BROOKLYN, NEW YORK.

ATTENDING PHYSICIAN TO THE WILLIAMSBURGH AND NORWEGIAN HOSPITALS; CONSULTING PHYSICIAN TO THE BETHANY HOSPITAL

A RATIONAL diet for typhoid fever should aim to meet in their totality the dietetic indications presented by that disease, and should avoid favoring particular indications at the expense of others. What are the dietetic indications which must thus be met by such a rational diet?

One group of these indications relates to the *quantity of the food.* The basis for the estimation of that quantity is naturally the minimum health ration for age, sex, and activity. The writer has been led by observation and experience to the opinion that the minimum health ration for a man of medium size lying in bed quietly should supply not far from 60 gm. of protein and fuel of a value of about 1600 calories. Modifications of these quantities in both directions seem to be called for by the conditions in typhoid fever. The fever and the increased metabolism constitute an apparent indication for more fuel if not more protein, while the lesions in the intestines, the depression of the glandular functions due to the toxemia, and the disturbance of metabolism generally from the same cause, seem to make more than ordinarily difficult the utilization of excess food. Clinical experience in this and other diseases favors the proposition that the ability to utilize food should be the determining factor rather than the theoretical requirement for an excess over the minimum health ration. It seems to be a natural instinct for all animals to diminish their intake of food when ill. This instinct shows itself strongly in man during the earlier stages of typhoid fever. But in that case, the instinct to diminish food is usually so disturbed by the toxemia of the disease that it becomes an unreliable guide, and to a certain extent forced feeding is required in the early part of the disease, that is, the patient needs to be fed more than he wants; while in the later stages he may require to be fed less than his hunger calls for. But in the latter period of the disease, and especially during convalescence, it is desirable and usually possible to exceed by a considerable amount the minimum health ration, for there is waste to repair; and in the febrile period it is desirable to give a quantity of food a little in excess of the minimum health ration if the patient shows ability to utilize it, which is often the case; though frequently the conditions of the disease call temporarily for a reduction in the quantity of food.

Another group of these indications relates to the *consistency of the food.* If clinical experience of many years, even centuries, has taught anything in regard to the diet in continued fevers, it is that a fluid diet is the best; and not sufficient to nullify the teaching of this extensive clinical experience, is the fact that a few hundreds or even thousands of cases of typhoid fever have recovered after receiving a diet which included bread, meat, hard boiled eggs, and vegetables. Not only is the well nigh universal clinical testimony in favor of a fluid diet for typhoid fever during the febrile period, but what seem to be obvious contraindications to any but a fluid or semifluid diet are found in the local condi-

tions in the intestines, viz., ulceration and catarrh, as well as in the toxemia and the conditions dependent on it.

Another group of these indications relates to the *digestibility of the food.* With an ulcerated intestine and digestive organs more or less depressed in their functional power by severe and continued toxemia, it is obvious that only the most easily digestible articles should be given, and, since we are restricted to fluids, only the most easily digestible fluids or semifluids. Milk is an ideal food in most respects, but in its whole state it is found to be difficult of digestion by many adults; and whole milk should not be given to typhoid fever patients. Fortunately milk can be modified so as to be made easily digestible, and so modified it can enter with advantage and largely into a rational typhoid diet. Thin cereal gruels and strained fruit juices are digested with ease, and are consequently eligible on that count for admission to the typhoid dietary.

Another group of these indications relates to the *fermentability and putrefiability of the food.* The unstable conditions in the alimentary canal render excessive fermentations there more than usually disturbing; and the unhealthy condition of the intestinal walls and the functional depression of the overworked liver and kidneys render highly undesirable the introduction into the alimentary tract of free purins or the production there of a large amount of putrefaction poisons. Cane sugar, egg albumin, and animal broths are contraindicated. The indication for animal broths in small quantities as medicinal agents to stimulate the digestive secretions is entitled to a brief notice; but that is not a dietetic indication, and as a therapeutic indication it is not a strong one nor one of extensive significance. If animal broths are given, they should be given strictly as drugs possessing toxic properties, with due regard to the harm they can do as well as the good.

Another group of these indications relates to the *food salts.* Man cannot live by protein and fuel alone. Absolutely essential to normal physiological functioning are the food salts. These, with the exceptions of sodium chloride, are secured in health almost wholly from the ordinary articles of food in the conventional mixed diet, particularly articles from the vegetable kingdom. In devising a rational diet for typhoid fever provision must be made for these salts. This can be accomplished easily and safely by including in the dietary the juices of certain fresh fruits and by adding a small quantity of sodium chloride, and perhaps also of a calcium salt.

Another group of these indications relates to the *water ration.* Indications for a large water ration are found in the toxemia and the desirability of free elimination through the kidneys and skin. Contraindications to a large water ration are often present in weakness of the myocardium and perhaps also in a degenerated condition of the kidneys. A rational conclusion in regard to the water ration would seem to fix it at a fairly liberal but not extraordinarily large amount.

Another group of these indications relates to the *palatability of the food.* Palatability should be regarded in any diet, but it is not a sufficiently powerful indication to counterbalance such indications as difficulty of digestion, fermentability, putrefiability, possession of a large purin content, or ability to produce irritation of a diseased intestinal mucosa.

A final group of these indications relates to the *complications which may arise in the course of the disease.* Complications in the gastrointestinal tract are most common, and may call for extensive modifications of the diet. These modifications usually consist in diminishing the amount of food, giving only the most easily digestible articles, or stopping all food temporarily.

In the light of the dietetic indications which are suggested in the foregoing brief discussion, the writer has devised the following plan of feeding in typhoid fever, which is formulated in three dietetic prescriptions, with modifications.

PRESCRIPTION 1.—*For the Febrile Period.*

6 A. M.—Give 8 ounces of a two-to-one mixture of milk and barley water, to which has been added 4 grains of sodium chloride.

8 A. M.—The same as at 6 A. M.

9 A. M.—7 ounces of orangeade made with the strained juice of one orange, one ounce of milk sugar, and water.

10 A. M.—The same as at 6 A. M.

12 M.—The same as at 6 A. M.

1 P. M.—The same as at 9 A. M.

2 P. M.—The same as at 6 A. M.

4 P. M.—The same as at 6 A. M.

5 P. M.—The same as at 9 A. M.

6 P. M.—The same as at 6 A. M.

8 P. M.—The same as at 6 A. M.

At any time during the day or night give water to drink, but not more than enough to bring the total fluid ingested to 110 ounces, unless the weather is very warm and the patient desires it. If the patient has a weak heart the fluid should not exceed 90 ounces.

This prescription supplies daily about 50 grams of protein and fuel of the value of about 1,350 calories. It serves as a basic diet, which should be modified so as to give the patient a larger quantity and a greater variety of food, according to the following schema:

Modifications of Prescription 1.

A.—The same as 1, with substitution of artificially soured milk in place of the milk and barley water feedings at 8 A. M., 12 M., 4 P. M., and 8 P. M.

B.—The same as 1, or 1A, with the addition of half an ounce of predigested cereal food to the milk and barley water mixture.

C.—The same as 1, 1A, or 1AB, with the addition of one ounce of cream to four of the milk and barley water feedings.

D.—The same as 1, 1A, 1B, 1C, 1AB, 1AC, 1BC, or 1ABC, with the addition of two feedings of the milk and barley water mixture during the night.

E.—The same as 1, or any of the above modifications, with the substitution of peptonized milk for the milk in the milk and barley water mixture.

F.—The same as 1, or any of the above modifications, with reduction of each feeding to 6 ounces.

G.—The same as 1, with substitution of barley water alone for the milk and barley water mixture, and omission of the orangeade.

H.—The same as 1, or any of the above modifications, with the addition of 10 grains of calcium lactate dissolved in 5 ounces of water at 7 A. M., 11 A. M., and 7 P. M.

The first four modifications of Prescription 1, viz. A, B, C, and D, if all are given, which is desirable, produce considerable variety in the diet and bring up the total quantity to more than the minimum health ration. Prescription 1, thus modified (viz. Prescription 1ABCD) supplies daily about 75 grams of protein and fuel of the value of about 2,200 calories. The last four modifications, viz. E, F, G, and H, are given to meet special indications which may arise in the course of the disease.

PRESCRIPTION 2.—*For the Transitional Period.*

6 A. M.—Give 8 ounces of a two-to-one milk and barley water mixture, to which has been added one-half an ounce of a predigested cereal food, one ounce of cream, and 4 grains of sodium chloride.

7 A. M.—7 ounces of orangeade, as in Prescription 1.

8 A. M.—7 ounces of well-boiled rice, cream of wheat, or similar cereal, with 5 ounces of milk and 4 grains of sodium chloride.

10 A. M.—8 ounces of artificially soured milk, or, if preferred, the same as at 6 A. M.

11 A. M.—The same as at 7 A. M.

12 M.—The same as at 8 A. M.

2 P. M.—The same as at 10 A. M.

4 P. M.—The same as at 6 A. M.

5 P. M.—The same as at 7 A. M.

6 P. M.—The same as at 8 A. M.

8 P. M.—The same as at 10 A. M.

This prescription supplies daily about 70 grams of protein and fuel of the value of about 2,100 calories. It can be given in the average case between the fifth and seventh day after defervescence.

Modifications of Prescription 2.

A.—The same as 2, with the addition of two feedings of the milk and barley water mixture during the night.

B.—The same as 2, or 2A, with the addition of a poached egg on toast to the 12 M. feeding.

C.—The same as 2, 2A, 2B, or 2AB, with the addition of a scraped beef sandwich to the 8 A. M. feeding.

Prescription 2B or 2AB can usually be given on the sixth or seventh day after defervescence, and Prescription 2C, 2BC, or 2ABC can usually be given on the ninth day. If there is no reaction to the meat poisons, shown by a rise of temperature, the patient is usually ready for a gradual resumption of ordinary diet. If there is a rise of temperature or other disturbance after the meat sandwich or poached egg, return should be made to 2 or 2A. Prescription 2ABC supplies daily about 90 grams of protein and fuel of the value of over 2,500 calories.

PRESCRIPTION 3.—*For the Convalescent Period.*

7:30 A. M.—Give 8 ounces of well-boiled cereal, with butter, milk, or cream; 2 slices of dry toast, with butter; the juice of one orange, plain, or as in prescription 1.

10 A. M.—8 ounces of artificially soured milk, or 8 ounces of the milk and barley water mixture described in prescription 2.

12 M.—8 ounces of a milk soup (cream of corn, celery, potato, carrot, or spinach), or 8 ounces of artificially soured milk; 2 ounces of lean boiled, broiled or roasted beef, mutton, lamb, or chicken; 6 ounces of boiled macaroni or rice, with butter, milk, or grated cheese; 2 slices of toast with butter; fresh fruit juice, viz., of orange, grapefruit, grape, or pineapple, to the amount of 4 ounces.

4 P. M.—The same as at 10 A. M.

6 P. M.—16 ounces of milk in which has been crumbled 6 ounces of old bread or toast; or four slices of toast with butter, 2 ounces of cream cheese or pot cheese and 8 ounces of the milk and barley water mixture, described in prescription 2.

10 P. M.—The same as at 10 A. M.

Orangeade, as in the preceding prescriptions, or similar fruit juice preparations, may be given freely at any time.

This prescription supplies daily about 90 grams of protein and fuel of the value of about 2,500 calories. It serves as a standard convalescent diet, which can be modified by additions and substitutions as convalescence progresses. It can usually be given on the twelfth day after defervescence. The fruits and vegetables should be added cautiously, especially those containing much cellulose.

The plan of feeding in typhoid fever above described was employed by the writer in a series of 200 cases of that disease which were treated by him in the Williamsburg and Norwegian Hospitals between June 15, 1910, and August 12, 1914. This series is a continuous one, and includes all the cases of typhoid fever treated by him in those hospitals during that period.

The number of deaths in this series of cases was eighteen, and the mortality was 9 per cent.

Following is a resumé of the fatal cases:

Case 1 entered the hospital with a double lobar pneumonia and died three days after admission.

Case 2 was taken from a ship in the harbor in the third week of the disease, and died of intestinal hemorrhage five days after admission.

Case 3 was taken from a ship in the harbor, probably in the third week of the disease, with pronounced signs of myocardial degeneration.

Case 4 entered the hospital in a moribund condition and died two days after admission; was in the eighth month of pregnancy.

Case 5 entered the hospital with lobar pneumonia.

Case 6 entered the hospital in the third week of the disease with pronounced signs of myocardial degeneration.

Case 7 entered the hospital in the fourth week of the disease; developed bronchopneumonia.

Case 8 was an ambulant case; walked into the hospital in poor condition; developed perforation of the intestine.

Case 9 was an ambulant case; walked into the hospital in poor condition; developed lobar pneumonia.

Case 10 entered the hospital in the third week of the disease and died of lobar pneumonia six days after admission.

Case 11 entered the hospital in the fourth week of the disease, and died of pneumonia seven days after admission; was 56 years old.

Case 12 was taken from a ship in the harbor, probably in the third week or later of the disease, with pronounced signs of myocardial degeneration, and died five days after admission.

Case 13 entered the hospital in a moribund condition, with pneumonia and intestinal hemorrhages, and died two days after admission.

Case 14 entered the hospital in a moribund condition, with meningitis, and died three days after admission.

Case 15 entered the hospital in the fourth week of the disease; developed perforation of the intestine.

Case 16 was an ambulant case; entered the hospital in the third week of the disease; died of intestinal hemorrhages three days after admission.

Case 17 was an ambulant case; entered the hospital with pronounced signs of myocardial degeneration and died three days after admission.

Case 18 entered the hospital in a moribund condition, with pericarditis, and died two days after admission.

An analysis of these eighteen fatal cases shows the following facts:

At least nine of them were in the third week or later of the disease when they were admitted to the hospital. At least six more were moribund on admission to the hospital. One other had pneumonia on admission. The remaining two were walking cases who entered the hospital in poor condition, and developed, respectively, pneumonia and perforation of the intestine. The average duration of life after admission to the hospital in eleven of the fatal cases was 3.5 days.

It will be seen from this analysis of the fatal cases that practically all the deaths occurred in patients who were unfavorable subjects for treatment when they entered the hospital.

It regularly happens that a certain proportion of the cases of typhoid fever entering general hospitals are unfavorable cases for treatment on account of previous neglect. This fact establishes an irreducible minimum mortality which is apt to be particularly large in hospitals which serve districts inhabited by the poorer and more ignorant classes of people. Both of the hospitals in which the cases reported in this paper were treated serve such districts. The Norwegian Hospital, in which three-fourths of these cases were treated, receives a large proportion of its patients from the water front of South Brooklyn and the adjacent tenement house districts, and also from ships in the harbor, many of which come from the tropics, and the Williams-

burg Hospital receives most of its patients from poor tenement house districts.

The treatment other than dietetic of the 200 cases of typhoid fever, whose report forms the basis of this paper, was conservatively symptomatic. For high temperatures, cold or tepid sponge baths were given during the first three years of the period, but not during the last year; during the last year no attempts at reducing the fever were made, either by cold water or other agents. For gastric irritability, changes were rung on the modifications of Dietetic Prescription 1. For diarrhea and tympanites, the diet was reduced to barley water alone, or water alone, or all food was temporarily discontinued. For intestinal hemorrhage, the diet was reduced to barley water alone, or all food was temporarily discontinued, and opiates were given, and usually calcium lactate or chloride also. For perforation of the intestine, all food was discontinued, and the case was referred to the surgeons for operation. For restlessness and delirium, bromides were given, rarely opiates. For myocardial weakness, strychnine and strophanthus were given in small doses. For constipation, a simple or soapsuds enema was given every second day.

The following clinical observations were made on the cases in this series:

1. The proportion of cases showing severe types of the disease, taking into account the entire period of over four years and the whole number of cases, appeared to be about the average found in general hospitals with public services in poor parts of the city.

2. Tympanites was practically unknown in this series of cases. If a patient came into the hospital with tympanites, unless he was moribund, it soon disappeared. This was one of the most striking observations made in connection with the use of this diet. It is interesting and instructive to compare with this series of 200 cases, in which tympanites practically did not occur, a series of 100 cases treated by the writer in the same two hospitals between July 8, 1906, and August 31, 1908. In that earlier series of cases, which were treated essentially in the same way as the present series with the exception of the diet, tympanites was a prominent symptom, occurring to a notable degree in nine cases; and the mortality in that earlier series was 14 per cent., as against 9 per cent. in the present series.

3. Intestinal complications were less frequent than was to be expected from the average severity of the cases in this series. Intestinal hemorrhage was noted in nine of the 200 patients, of whom three died, and perforation of the intestine occurred in two, both of whom died. In the earlier series of 100 patients cited above for comparison, who were fed on a different diet, intestinal hemorrhage was noted in seventeen, of whom ten died, and perforation of the intestine in two, both of whom died.

4. High fever and delirium, and also extension of the febrile course to four or more weeks, occurred with unusual frequency in the epidemic of the last of the four years which this series covers, yet the mortality in the cases of that last year was less than in those of the preceding three years; only two patients died out of sixty who were treated between June 15, 1913, and August 12, 1914, and both of those were moribund on admission to the hospital, dying, one in two days of pericarditis, and the other in five days of myocarditis. It is interesting to note that during this last year the use of cold water applications to reduce the fever, which previously had been a routine procedure, was discontinued. The patients seemed to do better without the antipyretic treatment; cases showing severe types of the disease were common, but they were unusually free from complications.

5. Marked emaciation was not a prominent symptom, except temporarily in cases with extreme toxemia. Twelve patients who were admitted to the Norwegian Hospital between September 10, 1913, and October 25, 1913, were weighed when they were discharged from the hospital, which was as early in convalescence as could be considered reasonably safe. These twelve patients were not selected cases, but were taken in regular order, with exception of two who escaped from the hospital before they could be weighed. They showed, on the whole, a rather severe type of the disease, a type which prevailed largely in the epidemic of 1913, and was characterized by a prolonged febrile course: the fever in these twelve cases, including recrudescences in two cases, averaged in duration 34.5 days. The average weight of these twelve patients when discharged from the hospital was 138 pounds, and their average height was 5 feet 6½ inches. Seven of them were able to tell what was their regular weight in health; it averaged 144 pounds, and their average weight when discharged from the hospital was 137.5 pounds.

1218 Pacific Street.

OIL-ETHER COLONIC ANESTHESIA.

By J. T. GWATHMEY, M.D.,

NEW YORK.

ANY new method of anesthesia must be placed in immediate competition and comparison with the best methods of to-day. Certainly, no one method (or anesthetic) will ever replace all others. However, if it finds a permanent place of usefulness it has accomplished all that may reasonably be expected. Is oil-ether colonic anesthesia worthy of such a place?

Luke,[1] using an imperfect technique, as shown by the tardy recovery of his patient, after three cases, offers many theoretical objections to the method, and reports the first death attributable in a measure to the anesthetic.

Let us study this case. "A fairly vigorous man of about fifty years; never really recovered from the anesthetic, and was in a most profound state of narcosis for nearly six hours. Six ounces of ether and two ounces of olive oil were administered in the usual manner, and both before and after the operation was completed the colon was repeatedly irrigated without apparent benefit. Operation, jaw resection. Patient died with an aspiration type of pneumonia twenty-two hours after operation."

The technique, as outlined, was faulty, in as much as no mention is made of chloretone or some other hypnotic (in addition to the hypodermic of morphine), which I have mentioned in every article I have written upon the subject.[2] The object of the chloretone solution is two-fold: (1) It diminishes the amount of oil-ether solution required; (2) it assists materially in gauging the susceptibility of the patient to this particular form of anesthesia.

The fact that "the colon was repeatedly irrigated without apparent benefit" indicates that too much of the anesthetic was given in the first place, and that the irrigation should have commenced even before the operation. As a last resort, an intraven-

ous saline injection of about 1,000 to 2,000 c.c. should have been given.

When an aspiration pneumonia occurs, it is partly due to the assistant's not keeping a clear airway by sponging or using a suction apparatus.

Eight ounces of a 75 per cent. solution of ether in oil will keep a patient weighing 160 pounds or over in surgical anesthesia for three hours, and no longer, provided a clear airway is maintained. This has been demonstrated repeatedly, twice in my own practice. A "six-hour profound narcosis" indicated an overdose or imperfect airway, or both.

It would be unfortunate if any one should be misled by theoretical considerations based upon faulty technique. The theoretical objections can best be answered by saying that the fundamental principles have been thoroughly worked out, both upon animals and in chemical laboratories, and, finally, in the Bureau of Laboratories of the Department of Health of New York City.

In order to determine the therapeutic value of oil-ether in ophthalmology, rhinology, dermatology, and other branches of medicine, tests are now being conducted by distinguished clinicians. Results will be reported later.

Clinical Findings.—The fundamental principles enunciated above have been carried out in over 500 cases in the New York Post-Graduate Hospital, People's Hospital, Columbus Hospital, Smith Infirmary, and by Drs. Foote, Meeker, Lumbard, Arrowsmith, Cantle, and myself, besides many others.

Condensing the experience gained from these 500 cases, it may be stated positively that:

1. This method compares favorably with any other method of administering ether, when the proper technique is employed.

2. The experience already gained justifies a continuation of the method.

3. The limits of safety are wider than with any other method, as shown by the difference between the dosage for surgical narcosis and for toxemia. This is well illustrated by the case of a patient who received four times the required amount of preliminary medication and two-thirds more of the mixture than is necessary, as we now know it, yet made an uneventful recovery.

The preparation of the patient is not different from the ordinary technique, with the exception of an irrigation until the return is clear, on the morning of the operation. Some surgeons employ this method whether rectal anesthesia is used or not.

The crux of the present situation resolves itself into the following proposition: Is there any class of patients whose lives are better safeguarded by the employment of oil-ether anesthesia? This can be answered emphatically in the affirmative.

I. It is *especially* indicated in the *very obese*. Here any inhalation method is attended with risk; spinal and local anesthesia are difficult; intravenous anesthesia is less objectionable than the others named, but is not so easy of application as with other patients. With rectal anesthesia, however, these patients go to sleep like babies and wake up as from a natural sleep. In every instance with this class of patients the nausea is negligible. This is well illustrated by the following cases:

Case I.—A patient weighing 250 pounds, in the Massachusetts General Hospital of Boston. In this case, Dr. Allen, the anesthetist, stated that he dreaded giving the patient any inhalation anesthetic.

Case II.—A patient weighing 240 pounds, in the New York Hospital for Ruptured and Crippled, operated upon by Dr. Walker, Drs. Coley and Gibney being present.

In both these cases the operation was for umbilical hernia. Relaxation was perfect, and the anesthesia was all that could be desired.

Case III.—A private patient operated upon by Dr. Forbes Hawkes, the patient weighing between two and three hundred pounds. As in all private cases, the nurses preceded us and followed our directions in regard to administration, our duty being to supplement withdraw, deepen, or lighten the anesthetic according to the indications. The result, as in the other cases, was ideal.

Many similar cases could be cited, but these should be sufficient.

II. Another class in which this method is especially indicated is composed of neurotics and those in whom the psychic element predominates. Two illustrations will suffice for this class.

Case IV.—An insane patient was brought to New York City for a surgical operation. The possibilities of trouble were very great, if the patient became aware of the proposed operation. A nurse administered the mixture, as directed; the patient fell asleep quietly, was placed upon the operating table, the operation was successfully performed, and the patient returned to bed without ever seeing a doctor.

Case V.—A boy, eight years of age, fell upon the ice and broke his arm. He was highly wrought up over the occurrence. In this instance, the surgeon, Dr. Harold Meeker, gave the mixture to the mother of the child who administered it to the little patient while he was lying on a sofa, the surgeon being in the next room. The child had no preliminary medication or preparation. He dropped to sleep quietly, the anesthesia being entirely satisfactory.

III. Dr. Arrowsmith of the Brooklyn Eye and Ear Hospital reports fifty cases, ten of which were esophagoscopies. He considers the method ideal for this class of work.

Undoubtedly, deaths will occur with this method as with all others if administered when contraindicted, or with faulty technique, and in fairness it should not be administered in borderline cases unless the physiology is thoroughly understood.

The anesthesia is completely under control at all times. If a lightening of the anesthesia is desired, a Connell breathing tube will give the necessary dilution of air. If the anesthesia is too light, a towel placed over the mouth and nose of the patient will deepen it. If the patient shows undue susceptibility to the ether, part or all of the mixture can be withdrawn immediately, if necessary, or at any time later. The *judgment* of the anesthetist as to the proper amount, in the first place, and if this be faulty, its immediate correction, etc., by the addition or withdrawal of the mixture, is the principal factor in making this a perfectly safe method.

The following cases from the Mary Gates Hospital, Port Arthur, Texas, will illustrate this idea. All three were borderline cases, and the anesthesia was a problem.

Case VI.—Female, weight less than one hundred pounds, incomplete abortion of three weeks standing; pulse 150. As a preliminary, morphine, gr. 1/8, atropine, gr. 1/150, chloretone, gr. 10; anesthetic, ether-oil, 75 per cent., oz. 4. Patient completely anesthetized in ten minutes. Patient did not vomit, and three hours after the operation asked when the doctor was coming to operate. Left the hospital four days later.

Case VII.—Woman, weight 70 pounds; panhysterectomy. Morphine, gr. 1/8; atropine, gr. 1/150; chloretone, grs. 10; anesthetic, ether-oil, 75 per cent., oz. 4. Was not under the influence of the anesthetic in twenty minutes, so was given two ounces additional, and in five minutes was completely anesthetized. When brought into the operating room the patient was too deeply narcotized, so two ounces were siphoned off. The operation lasted two hours and forty-five minutes. In coming out the respirations were unsatisfactory, and

patient was given, by hypodermic, cocaine, 1/2 gr. Patient did not vomit nor ask for water and made an uneventful recovery.

CASE VIII.—Female, weighing 165 pounds. Operation for gallstones. Almost imperceptible pulse. Preliminary: Morphine, gr. 1/4; atropine, gr. 1/150; chloretone, gr. 10; anesthetic, ether-oil, 75 per cent., oz. 8. Pulse improved immediately. After establishing ether tension, the patient seemed a little too deeply under, so three ounces were siphoned off before the operation began; supplemented with chloroform when operating on gall-bladder. Operation lasted one hour and thirty minutes. Patient reacted immediately upon irrigation, and made an uneventful recovery, without vomiting.

The anesthetist should know that with this special form of anesthesia the breathing is quiet, *as in natural sleep;* the reflexes, especially the lid reflex, may be quite active, and yet the patient be in a state of deep surgical anesthesia. Cyanosis and stertor should be checked by the use of a breathing tube. We would further suggest that previous articles on this subject be carefully read before one attempts this method of anesthesia.

With these suggestions in mind, we have no hesitation in submitting an abstract of the technique, by Dr. Charles Gordon Heyd, former resident house surgeon, New York Post-Graduate Medical School and Hospital, for the benefit of those who may wish to use this method.

I. Preparation of Patient.—(*a*) A mild laxative the night before operation, avoiding all purging. On the following morning an ordinary "soap-suds" enema is given to assist the evacuation of the bowels. (*b*) Irrigation of the colon until the return is clear, three hours before the operation.

II. Indications.—(*a*) Especially indicated where the element of fear is in evidence, as in goiter cases. (*b*) In the very obese. (*c*) Bronchoscopy and gastroscopy. (*d*) All operations upon the respiratory tract, head, neck, and chest.

III. Contraindications.—(*a*) Whenever ether is contraindicated, *except* where the patient had been ill from a previous administration. In these cases it can be given with impunity. It can also be given in bronchitis, asthma, etc. (*b*) Pathological conditions of the lower bowel, colitis, hemorrhoids, fistula, etc. (*c*) When the patient complains of considerable rectal pain upon the introduction of the oil-ether solution.

IV. Apparatus.—(*a*) A small catheter and a funnel for the introduction of the oil-ether solution. (*b*) A Gwathmey rectal tube with which to flush or withdraw fluid from the rectum.

V. Administration.—(*a*) One hour before operation visitors should be excluded, the room darkened, and quiet maintained. The patient should not now be left alone. Then give per rectum: Chloretone, gr. 5-20; ether and oil, aa. dr. 2-4. Or a suppository: Chloretone, gr. 5-20, or some other hypnotic of equal value.

(*b*) Half an hour before operation, by hypodermic injection: Morphine, gr. 1/8 to 1/4; atropine, gr. 1/200 to 1/100.

(*c*) Twenty minutes before operation, give the oil-ether as follows: (1) Mixture for adults, olive oil, oz. 2; ether, oz. 6. (2) Mixture for weak, anemic patients, olive oil, 45-35 per cent.; ether, 55-65 per cent. (3) Mixture for children, ether-oil, 50 per cent.

Patient in bed in the Sims position. The catheter is well lubricated and inserted 4 inches within the rectum. The mixture is poured slowly into the funnel, at least five minutes being consumed in its introduction. Introduce one ounce of oil-ether solution for every twenty pounds of body weight, except for obese persons. The eight ounces should never be exceeded with any patient. *If patient goes to sleep before required amount is given, stop.*

VI. Danger Signals.—(*a*) *Loss of lid reflex.* (*b*) *Stertor or embarrassed respiration.* (*c*) *Approaching cyanosis.*

If any of the above signs are present, immediately withdraw two or three ounces of the mixture from the rectum. If the breathing is regular, with reflexes active, the patient will be relaxed and in surgical narcosis.

VII. Post-operative.—Immediate irrigation of the rectum with cold soap-suds, at the same time massaging the colon quietly from right to left, thus expelling any liquid which may be left. Then introduce two to four ounces of olive oil and one pint to one quart of cold water. Withdraw tube from rectum.

Further after-treatment, the same as after other forms of anesthesia.

Latest Technique.—Recently the technique has been still further improved by diminishing the amount of the oil-ether mixture one-third to one-half. This has been accomplished by using paraldehyde as the preliminary. Paraldehyde has been employed as an hypnotic in many hundreds of thousands of cases in insane institutions and general hospitals. When employed in connection with ether it intensifies the action of the anesthetic, giving more complete relaxation without in any way affecting the pulse or respiration.

The prescription for this preliminary is as follows: Morph. alkaloid, gr. 1/8; paraldehyde, dr. 1; ether and olive oil, aa, dr. 3½.

This one-ounce solution should be administered per rectum one hour before the operation instead of the chlorestone. When this preliminary is given, the technique as outlined above should be followed, except that instead of a hypodermic this dose should be repeated for athletes, alcoholics, and patients weighing over 160 pounds. For the average patient do not repeat the dose.

One dram of paraldehyde used in this way is equivalent in anesthetic value to two ounces of a 75 per cent. oil-ether mixture. We now give six ounces of the oil-ether mixture where we formerly used eight. When the paraldehyde is repeated, for the cases mentioned, we give four ounces instead of eight. This procedure is so satisfactory that we never use more than two drams of paraldehyde for any patient. This paraldehyde mixture, when used as a preliminary to nitrous oxide and oxygen, renders any further addition of ether by inhalation unnecessary; gives a greater relaxation, and the ether and paraldehyde are not noticeable to the patient.

40 EAST FORTY-FIRST STREET.

Ossiculectomy.—E. D. Davis reports the case of a man aged 36, with chronic attic suppuration of the left ear, treated by intratympanic syringing, etc., with no improvement. There was required a submucous resection, and with the same anesthetic ossiculectomy was performed. The patient had arrested pulmonary tuberculosis.—*Proceedings of the Royal Society of Medicine.*

INFECTION OF THE MIDDLE EAR WITH BACILLUS TUBERCULOSIS AND BACILLUS COLI.

By GEO. B. LAKE, M.D.,

CAPTAIN MEDICAL CORPS, U. S. A.,
JOLO, MORO, P. I.

On January 8, 1909, Mr. D. J. B. presented himself at my office for treatment and gave the following history: He is an American, 39 years old, of medium height and stocky build (weight about 200 pounds) and of a fair, florid complexion; married; by occupation a farmer.

His *family history* showed nothing bearing upon his case.

Personal History.—At six years of age he suffered from earache, and at this time a discharge from his left ear was noticed. From that time to this the discharge has persisted, more or less free, and with short intermissions from time to time. Since 1882 this discharge has had a very foul odor, so much so that he feels himself to be almost an outcast from society on account of it. At times there is a slight pain in the ear, but it is never severe. He has a continual, hacking, unproductive cough, and feels weak, tired, and nervous a good deal of the time. There has been no noticeable loss of weight. His kidneys act regularly and freely, but his bowels are constipated most of the time.

The general physical examination showed a large, well-nourished man, inclined to stoutness, with a rather sluggish, florid skin, but presenting no evidences of general disease. Examination of the throat showed him to be suffering with a moderately severe, subacute follicular pharyngitis.

Uranalysis.—Total quantity in 24 hrs., 1,300 c.c.; color, amber (clear); odor, aromatic; sediment, very slight, flocculent; specific gravity, 1,018; total solids, 54.6 gm.; acid index, 30; acid units, 39,000; indican, none; total urea, 13.0 gm. (1 per cent.); albumin, none; sugar, none. Examination of the ear was unsatisfactory, as the external canal was entirely filled with a dark-red, spongy-looking mass, through and around which oozed thin, greenish-yellow pus, having an inexpressibly fetid odor. The microscopic examination of the discharge was made in the bacteriological laboratory of the Indiana State Board

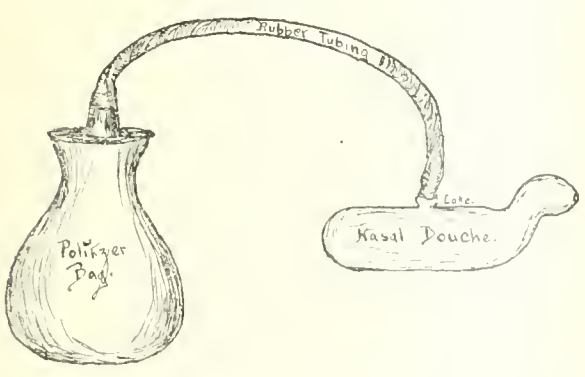

Fig. 1.

of Health, and the following report was rendered: "The specimen of discharge from the ear of D. J. B. contains remarkably large numbers of tubercle bacilli. It is rather rare, of course, that these organisms are found in the discharge from a tuberculous middle ear, and the finding of such large numbers makes the case rather unusual."—J. P. Simonds, M.D., State Bacteriologist.

A specimen of sputum was sent to the same laboratory and reported upon as follows: *B. tuberculosis*, none; streptococci, numerous; pneumococci, numerous; pus cells, many.

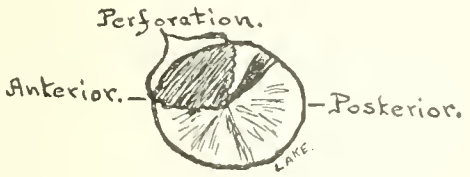

Fig. 2.

Treatment and Subsequent History.—The case was accepted with a very guarded prognosis, and the treatment, pending the receipt of the bacteriological reports, was tentative, consisting of remedies for the relief of the pharyngitis (including a thorough cleaning of the bowels with calomel and magnesium sulphate), and douching the ear as well as possible with mild alkaline antiseptic solutions.

After the receipt of the above reports the patient was placed upon vigorous antituberculous treatment of a general character, although a von Pirquet test, made on March 10, with 1 5per cent. strength of Koch's old tuberculin, was negative.

On March 4, 1909, a polypus 1 cm. in diameter was removed from the posterior wall of the left external auditory canal, which, when submitted to bacteriological examination, was reported upon as follows: "The section of aural polyp from the ear of D. J. B. shows no evidence of tuberculosis. It is made up of cells quite similar to those found in nasal polypi, namely, large cells containing material that appears to be mucoid in character. In addition to these cells there are areas of various sizes, many of them relatively large, made up of small round cells. No giant cells were found. Some time ago you sent us a smear of the discharge from Mr. B.'s ear, which showed remarkably large numbers of an acid-fast bacillus which resembled, morphologically, the tubercle bacillus in every respect. Of course it is possible that the tuberculous process and the polyp might have been coincident and more or less unrelated conditions in the ear, or the presence of the large amount of round-celled infiltration in the polyp itself may indicate that it is really due to the infection of tubercle bacillus, in spite of the fact that the condition was not typical of tuberculosis, in that it contained no giant cells and no areas of coagulation necrosis."—J. P. Simonds, M.D., Bacteriologist.

Following the removal of the polypus the patient received, twice weekly, in addition to the general treatment, injections into the ear of Beck's bismuth paste (bismuth subnitrate 33 parts, vaseline 67 parts). The above treatment was continued for about six weeks, during which time the patient's general condition improved, and the aural discharge diminished in quantity and in offensiveness, although, on March 13, a specimen of the discharge was reported to contain many tubercle bacilli.

During the month of May, 1909, the patient was careless about reporting for treatment, and as a result the discharge became more profuse and fetid. Treatment was resumed with regularity about the first of June, consisting, in addition to the general dietetic and hygienic treatment, of washing the ex-

ternal auditory canal with various antiseptic solutions (1 to 2,500 bichloride of mercury, 1 to 3 solution of hydrogen peroxide, liquor antisepticus, and various others were tried), and injecting the bismuth paste under pressure.

Once more the symptoms rapidly improved, but the ear still presented an abnormal appearance, and on June 28 a second polypus was diagnosed and several attempts made to engage it in a snare and remove it. These were unsuccessful, both on this and several other days, and it was finally decided to destroy the polyp with silver nitrate fused on the end of a probe. After several treatments the growth began to disintegrate, and the lunar caustic was applied, once or twice a week, until the first of September, when the external canal was practically clear.

The general treatment was continued, and also the local treatment to the ear. The patient's general condition improved markedly during this time, and when the local treatments were regular the ear was much better, but when a treatment or two was missed the discharge increased and became more foul.

A specimen submitted November 10, 1909, was reported on as follows: "The examination of the specimen of aural discharge received November 10 shows no tubercle bacilli. On March 13 we received a specimen of aural discharge from this same patient in which we found many tubercle bacilli. Whether the absence in this case means that the tuberculous process has entirely subsided or whether, for some reason, the bacilli have suddenly become so few in number that they could not be found, it is impossible for me to say just from examining the specimen. There is still a rather severe mixed infection, however, for the specimen contained many pus cells and great numbers of all sorts of bacteria."—J. P. Simonds, M.D., State Bacteriologist.

The case continued in about the same status throughout the winter, and spring found both physician and patient well nigh discouraged. However, having had some very encouraging results from the use of bacterial vaccines during the winter, I decided to see what could be done with them in this case, and early in April, 1910, I sent a specimen to the laboratory of H. K. Mulford & Co. for examination, which was reported upon as follows: "—— I beg to report to you that there were a number of different bacteria in the culture and it is hard to tell just which are contaminations. The smears you sent, however, showed a bacillus to be rather prominent and a bacillus morphologically similar grew in the cultures. This bacillus seems to have some of the characteristics of the *B. coli*, although we have not had time to work it out. I have given instruction to have an autogenous vaccine made—50 millions of these bacilli per c.c.————"

Signed: A. Parker Hitchens,
Director Biological Laboratories.

The vaccine arrived early in May, and on the 12th of that month treatment with it was begun, and 13 doses were given, as follows: May 12, 50 million killed bacteria; May 18, 75 million; May 25, 100 million; May 31, 125 million; June 8, 150 million; June 20, 175 million; July 2, 200 million; July 10, 250 million; July 17, 300 million; July 31, 350 million; August 7, 375 million; August 14, 400 million; August 20, 425 million.

About the time the vaccine was started the general treatment was suspended, as his condition was good. The local treatment to secure cleanliness of the ear was continued.

Having read, somewhere, the very rational suggestion that, in using bacterial vaccines in the treatment of local affections, better results followed when the parts were occasionally rendered hyperemic, thereby insuring the contact of larger amounts of the antibodies with the diseased areas, I searched the instrument catalogues for an apparatus to produce hyperemia of the middle ear. Failing to find what I wanted, I devised an apparatus with a Politzer bag and a Birmingham nasal douche, which worked very well (see Fig. 1). This was used each time an injection of vaccine was given.

On July 10 normal cerumen appeared on the applicator for the first time, and by the end of the month, there being at that time no discharge and no odor, the patient felt that he could resume social intercourse with his neighbors without embarrassment.

The treatment was, however, continued until the end of August, at which time his tympanum appeared as shown in Fig. 2, and his ear was, save for the scars of battle, to all appearances a normal ear. The patient felt that he was cured and refused further treatment.

In September I left the town for new fields of labor, but, being much interested in the case, I wrote to the patient two years later to learn what his condition was, and, under date of October 31, 1912, received a letter from which the following is a quotation: ———"about the ear. It is not well, but better than it was before treatment. There is some discharging yet and that offensive odor, but not so bad as it was. I believe that if we had continued the serum treatment that I would have been cured. ————"

The patient had evidently discontinued all treatment after my departure, but I agree with him in thinking that, had the vaccine treatment been followed up, there was a reasonable prospect of a complete cure, in view of the fact that more was accomplished by this form of treatment in four months than had been achieved by other methods in twenty-eight years, at least one year of which treatment I can certify was painstaking and thorough.

A study of this case seems to warrant a few suggestions.

1. One cannot treat middle-ear affections satisfactorily until the external canal is rendered as nearly normal as possible.

2. Beck's bismuth paste is a remedy which should be given a trial in most cases of localized tuberculosis which are accessible to it.

3. When one cannot buy an instrument one needs one can often extemporize a substitute from materials at hand which will do the work very satisfactorily.

4. If one has not a thoroughly equipped laboratory and the skill to use it to the best advantage, he should always avail himself of the facilities afforded by the laboratories of the various State Boards of Health, or those in the cities which do such vaulable work for the country practitioner at very moderate fees.

5. Local measures alone in chronic middle-ear infections bring little satisfaction to the patient or honor to the physician, no matter how diligently applied.

6. In any local, chronic, infectious process which is caused by an organism that can be grown in the laboratory, the use of autogenous bacterial vaccines should never be forgotten or neglected.

ABDOMINAL ANEURYSM AS A CAUSE OF LEFT-SIDED ABDOMINAL PAIN.*

By EDWARD H. GOODMAN, M.D.,

PHILADELPHIA.

ASSOCIATE IN MEDICINE, UNIVERSITY OF PENNSYLVANIA.

In this paper, attention is called to aneurysm of the abdominal aorta as a hitherto undescribed cause of left-sided abdominal pain. This variety of aneurysm is rare in comparison with aneurysm of the thoracic aorta, only 16 cases being seen in 16 years among 18,000 admissions to the Johns Hopkins Hospital, the ratio of abdominal to thoracic aneurysm being about 1 to 10.

The incidence, however, seems to vary in different localities. In Vienna, of 19,300 necropsies, there were only 3 cases among 222 cases of aneurysm. Of 468 cases of aneurysm at St. Bartholomew's Hospital, there were 23 of the abdominal aorta (1 to 20). In Guy's Hospital, of 18,678 autopsies, there were 325 aneurysms and of these 54 were of the abdominal aorta. (Osler, *Lancet*, October 14, 1905.)

As far as the recognition of the condition is concerned the obscurity of its symptoms renders its correct diagnosis very difficult. Bryant states that of the 54 cases in Guy's Hospital, only 18 were correctly diagnosed. When of the anterior wall of the aorta, the most obvious feature of the disease is a palpable expansile tumor, while aneurysms of the posterior wall are difficult to diagnose inasmuch as their chief symptom is pain, with absence of tumor. Any light which can be thrown on this difficult diagnostic problem therefore, is to be warmly welcomed.

Rare as abdominal aneurysm no doubt is, I have met with three cases during the past year, an unusually large experience considering its infrequency. The first case was not correctly diagnosed until operation, while diagnosis in the second case was confirmed at autopsy and that of the third was corroborated by the *x*-ray examination. The second and third cases were diagnosed on the left-sided pain alone, after excluding the usual causes of pain in the left hypochondrium. (Flatulence, surgical disease of the kidney, adhesions about an enlarged spleen, cancer of the splenic flexure of the colon.)

Case I.—Adler Brown, colored, aet. 46, fish cleaner. Admitted to Philadelphia Hospital (service Dr. Allyn), September 29, 1913, complaining of pain in left side of abdomen, which he says has been present only six weeks. He states that he becomes weak on exertion. Pains gradually became more severe until admission. The patient has used alcohol moderately, and has had a Neisserian infection. On examination, the abdomen was negative except for vague areas of tenderness. Heart negative. On October 10, 1913, the patient complained of steady pain in the abdomen. Since admission, patient has been kept in bed. On October 27th he was allowed to get up, but he developed so much pain in the left side that he had to go back to bed. On October 29, 1913, while straining at stool in the toilet room, he was suddenly seized with an agonizing pain in the left side of abdomen. This was so severe that he fainted and fell on the floor. I saw the patient about two hours after this accident, and found him to be suffering a great deal with pain in the abdomen, particularly on the left side of the abdomen midway between the ribs and the pelvis. The left hypochondrium was markedly hyperesthetic, the slightest touch seeming to give great pain. The abdomen was distended and on account of the tenderness deep palpation was impossible. Temperature was 100; pulse 120. Respiration 26. Leucocytes 23,400. Based on the sudden onset, the left sided pain, the pulse rate and the leucocytosis, a diagnosis of diverticulitis was made.

The patient was operated on by Dr. Carnett about five hours after the onset of the trouble. At the time of operation there was a bulging of the abdomen on the left side about the level of the umbilicus. Incision was made over this area and revealed large blood clots extra peritoneally. The peritoneal cavity was filled with masses of clotted blood. Palpation of the aorta disclosed a ruptured aneurysmal dilatation of the aorta at about the level of the diaphragm. The patient rallied after the operation but died early the next day (October 30, 1913) suddenly after vomiting large quantities of blood.

Owing to failure to secure a timely permission for an autopsy the body was removed from the hospital before an autopsy could be performed.

Case II.—Matthew Jackson, 39, laborer, colored. Admitted to Philadelphia Hospital (Service of Dr. Allyn), October 19, 1913, complaining of misery across chest, small of back and between shoulder blades. History of present illness: In January, 1913, he began to have pain in the left loin which would come on about once a week, and would persist for several days. The pain was described as dull and steady in character and was very severe, although not severe enough to prevent him from working. From January until the second of September, 1913, the pain persisted in the left loin, but at this time the patient began to have pain in the left chest and shoulder, radiating down the left arm. At times these pains are anginal in character, and occasionally wake him from a sound sleep. At these times the patient has great difficulty in getting his breath, but otherwise dyspnea is not a prominent symptom. Digestion is poor, appetite poor, belches a good deal, bowels very constipated, often not moving for four or five days. Micturition, frequent-dribbling. No nervous symptoms. Social history: The patient is a stevedore; alcohol moderately; cigarettes to excess. Had measles in childhood, acute articular rheumatism in 1907. Chancer, 1907. Tonsillitis, 1910.

Examination: Patient is a large well developed negro, electing to lie on the left side with legs drawn up on abdomen. Pupils are equal. Pulses equal. The patient is very tender over the left chest and over left side of abdomen and there is hyperesthesia of the skin over this area. Posteriorly tenderness extends from angle of scapula down. There is dullness over middle of chest anteriorly at level of the third rib extending slightly to right of sternum. Posteriorly there is a slight visible pulsation between the scapula. Heart enlarged, no murmurs.

In addition to the above, a subsequent note states that there is an area of dullness along the vertebræ at about the lower thoracic vertebræ, at which point there is marked tenderness. On November 1, 1913, the diagnosis was made of aneurysm of the lower thoracic or abdominal aorta. The main sign in this man's case was marked pain and tenderness over the left side of abdomen and lower chest. An *x*-ray showed a large aneurysm of the arch of the aorta, and on November 24, an *x*-ray taken for aneurysm of the abdominal aorta, confirmed the clinical diagnosis of this condition. *X*-ray report says: "There is evidence of a mass in upper left abdomen which may be an aneurysm if stomach was empty at time of exposure." Wassermann reaction strongly positive. Patient died suddenly December 19, 1913.

Autopsy 21 hours after death (Dr. Funk): Left-sided hemothorax. At a distance of 5 centimeters above the aortic orifice there is a small saccular dilatation communicating with the main trunk by an orifice which measures 1.5 centimeters in diameter. Just at the beginning of the descending portion is a dilatation which is directed backwards and is adherent to the vertebral portion of the 4th, 5th, 6th ribs. The 4th rib is involved in the erosion for a distance of 24 millimeters, the 5th for 70 millimeters and the 6th for 50 millimeters. The sac has also eroded portions of the corresponding vertebræ. Another dilatation appears at the level of and involving the 8th, 9th, and 10th thoracic vertebræ. Here again is a saccular dilatation which is directed backwards and which does not have a communication with the previously described sac, but the walls have become adherent to each other and their line of contact. This sac, posteriorly, is adherent as already mentioned to the 8th, 9th, and 10th thoracic vertebræ and also involves the adjoining ribs. The vertebræ show marked erosion of bony structure, but

*Presented before the American Gastro-Enterological Society, June 22-23, 1914.

no involvement of the intevertebral discs. There is an opening into the sac at the level of the 5th rib posteriorly through which protrudes a mass of partly organized blood clot. The abdominal aorta shows a slight thickening of the aorta.

Pathological Diagnosis: Multiple aneurysms of arch, ascending and thoracic aorta with rupture of one (lower thoracic). Congestion of liver and kidneys. Fatty infiltration of the liver. Atheroma of aorta. Partial atelectasis of left lung. Adhesive pleuritis. Caseous peribronchial lymph nodes. Hypertrophy of mesenteric and retroperitoneal lymph nodes.

Case III.—At present under my care, is a woman 70 years of age, who has been complaining of pain in the left side for the past three months. The pain seems to start in the left side of the back and runs anteriorly to the abdomen about a hand's breadth below the left costal margin. The pain is not continuous, at times she scarcely notices it and at other times it is severe. It is described as a dull, heavy, boring pain. It is referred to the left iliac fossa at times. Physical examination was negative except for tenderness in the left side and a systolic murmur in the epigastrium.

Having in mind the two cases previously described, I suspected abdominal aneurysm, as all other causes of the pain could be excluded. An *x*-ray examination, also a fluoroscopic examination was made March 10, 1914, by Dr. Pancoast, and revealed the presence of a moderate sized aneurysm of the abdominal aorta, or lower thoracic aorta. The *x*-ray plate is not defined enough to permit of reproduction.

There was in this woman's history nothing which might be considered an etiological factor in the production of an aneurysm (exertion, alcohol, syphilis). On closer questioning the patient stated that she had been in a railroad accident about a year and a half previously. The coach in which she was sitting went over an embankment, and she suffered severe injuries, fracture of left clavicle, fracture of left scapula, contusions of back, left side and leg, besides experiencing a serious nervous shock. This accident, with its resultant external violence without a doubt furnishes the most important etiological factor.

After having seen these cases of pain and tenderness in the left hypochrondrium, the records at the Philadelphia Hospital were searched for similar instances. Only one was found in which there was a sufficiently clear history with postmortem note. The other cases lacked autopsy control or the histories were too vague to be of any help.

Case IV.—Archibald MacDonald, 64, cooper. Med. C 656. Admitted Philadelphia Hospital (service Dr. Tyson), August 11, 1909. Died August 19, 1909. Chief complaint: Pain in left side of back and abdomen, radiating to left thigh. For the past eight months patient has been complaining of the above. Pain is continuous but becomes more intense at times and has been more intense for the past seven days. On examination a pulsation is present over the left side of the abdomen, being most marked at a point about midway between spine of the ileum on the left side, and the lowest rib of the same side. There is a slight amount of rigidity and palpation or percussion elicits pain. No mass can be felt. Impossible to lie on left side. In the left lumbar region patient is also tender. A diagram affixed to the history shows an area of pain and tenderness on the left side, between the ribs and the crest of the ileum. *X*-ray: "No characteristic shadow is visible."

Autopsy. (Dr. Wieder): The aorta when traced from the arch downward shows general dilatation of the lumen with thinning of the coats, in addition to a general fatty atheroma. Shortly after it pierces the diaphragm the continuity of the wall is broken for a space about 7 centimeters on the posterior aspect. The defect widens out in a very large thin-walled sac, which extends to the left of the median line all the way down to the brim of the pelvis. This is filled with a brownish organized blood clot. The bones of the 12th dorsal, and of the first and second lumbar vertebræ are extremely eroded. The lower portion of the abdominal aorta shows atheroma without calcification and no particular dilatations.

Pathological diagnosis: Ruptured saccular aneurysm of abdominal aorta. Fusiform dilatation of arch and thoracic aorta. Atheroma of aorta and of coronary arteries. Unfortunately the hospital notes are very incomplete and no record of course of illness during stay in hospital is given. Details concerning death are also lacking.

Osler (*loc. cit.*) quotes at length in his series of 16 cases the history of two patients, both of whom complained of pain in the left side of the abdomen. In Case III, the pain dated from 20 months previously when he had first a sharp stabbing pain in the left side. The pain had various qualities but radiated chiefly to the back and there was tenderness over the left side of the back and abdomen. In Case XVI the onset occurred six months previously with constant, dull, aching pain in the left flank. In both these cases, however, the diagnosis was facilitated by the finding of a large pulsating abdominal tumor.

According to Murray ("Reynolds' System of Medicine," 1879, Vol. V, p. 56) if the aneurysmal sac spring from the anterior aspect of the aorta, it will protrude in front, forming a considerable pulsating tumor, while if it spring from the posterior aspect, it will be bound down by fasciæ or other structures and protrude but little. These posterior aneurysms, although they pulsate and protrude but little, lead to serious results by pressing on important deep-seated parts. Nervous pains form the chief symptoms of aneurysm, and it is important that one should know the anatomical relation of anterior and posterior aneurysms to the nerves in which the pain is chiefly seated. An anterior aneurysm which springs from the anterior aspect of the aorta and protrudes forward, will compress the ganglia, plexuses, and branches of the abdominal sympathetic system, while a posterior aneurysm presses on the roots or branches of the spinal nerves as they issue from the intevertebral foramina. Hence it is that posterior aneurysms excite paroxysmal and radiating as well as continuous pains in the back and loins in a large number of cases; while anterior aneurysms excite pain in the epigastrium in a large number of cases, and pains in the loins with paroxysmal and radiating pains in but a small number of cases. In other words anterior aneurysms press on the sympathetic nerves of the abdomen, while posterior aneurysms press on the spinal nerves and their branches.

While posterior aneurysms frequently produce erosion of the vertebra, and anterior aneurysms produce erosion but rarely, no doubt relationship can be established between pain and erosion. Habershon and others have shown the truth of this statement, for cases are recorded in which there was pain of the most acute nature in the loins, and after death, the vertebræ were found to be free from erosion, and a painless illness has frequently been known to precede death when the vertebræ were found to be extensively destroyed.

In all three of my cases the aneurysmal dilatation was on the posterior wall of the vessel (absence of pulsating tumor character of pain). In Case I an autopsy was not performed so we are uncertain as to erosion of the vertebræ. In Case II, however, erosion was very marked. In Case III, now living, erosion is unlikely at the present writing (negative *x*-ray). Case IV exhibited a pulsating tumor with the characteristic left-sided pain and it is probable that there was dilatation of both the anterior and posterior walls.

The pain in the left side between the ribs and the crest of the ilium is described by the several patients as boring in character and may be continuous at times and at times intermittent. Case II describes her pain as involving the entire left flank, apparently radiating from a point in the mid-axillary line at the level of the umbilicus to the back. Case II had continuous pain, which some-

times moderated, but at times there were intense exacerbations of the same. A certain posture is assumed for relief. Case IV could not lie on left side, while Case II preferred this position. Case III is more comfortable when lying on the back or on the right side. In every case there was cessation from the pain at times.

Conclusion.—The diagnosis of abdominal aneurysm may be a matter of great difficulty. In the cases where the aneurysm springs from the anterior wall of the aorta, the diagnosis is materially facilitated by the finding of a pulsating tumor, but in dilatations of the posterior wall the customary signs of aneurysms fail. In all cases with obscure left-sided abdominal pain (with at times hyperesthesia over the painful area) for which no adequate cause can be found, and which fail to exhibit signs of abdominal disease, aneurysm of the abdominal aorta should be considered as a cause. A fluoroscopic examination with careful *x*-ray photographs is of valuable assistance in arriving at a correct diagnosis.

248 South Twenty-first Street.

THE COUNTRY PHYSICIAN AND CONGENITAL CLUB FOOT.*

By JOHN C. SCHAPPS, M.D., F.A.C.S.,

BUTTE, MONTANA.

The country doctor, master of emergencies, controller of conditions, is dismayed at the infant with the club foot. The foot, now cartilaginous, soft, plastic, will grow harder day by day. He is between the devil of an undertaking to which he feels he cannot do justice and the deep, cold sea of letting the days of opportunity slip neglected away. And it is not always in the early days only that the foot must be treated at home. A case must sometimes be carried through a long course of treatment to a successful finish or remain a perpetual discredit in the community. As a matter of fact, the cure, if commenced early and conducted according to a few simple working principles, is much easier than it looks. And it is my hope that in this brief and untechnical paper the physician will find something which will help him to meet this emergency with immediate confidence and ultimate satisfaction.

For brevity, I will deal with only that most common (and difficult) form of club-foot in which the toes point inward, the outer side of the foot is directed downward, and the heel is drawn up. The treatment naturally divides itself into three phases: the correction, the retention, and the release. The foot is not corrected until the deformity has been reversed and the foot remains or can easily be held

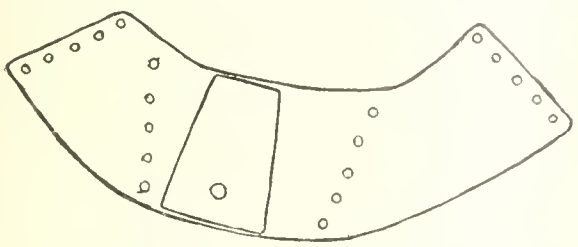

Fig. 1.—The author's club-foot holder.

so that the toes point upward and outward, the arch which was deeply concave has been obliterated or even replaced by a convexity, and, especially, the heel is well down. The soft young foot can be gradually but rapidly and painlessly bent into the desired shape by the Judson method which is described in most textbooks upon the subject by a

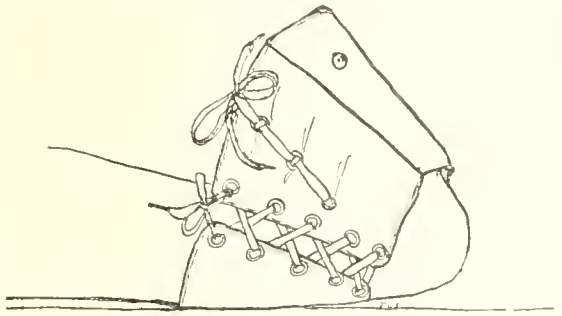

Fig. 2.—Club-foot holder applied.

series of plaster dressings or by some other means, the points being to well correct the lateral before beginning upon the anteroposterior deviation, to turn the feet quite out and up, to make the flexion at the ankle rather than at the middle of the foot, and to keep in close touch with the case. The correction is not difficult if made early, but the most thorough correction is useless if not followed by efficient retention.

The important central truth in both correction and retention is that a club-foot of this sort is not a foot which has been pressed out of shape by external force which ceases at birth, but a foot drawn out of shape by an internal process continuing and increasing after birth. The treatment is directed not against a deformty but against the tissue contraction of which the deformity is but the outward and visible sign. Failure to appreciate the distinction permits feet which seem beautifully corrected to relapse. The severity of a club-foot (for club feet, even those of the same child, differ greatly in severity) and the progress one is making in its treatment are estimated by the hand, not by the eye. The tendency to relapse is not overcome until the bones have acquired the necessary form and firmness to resist the deforming tension and the tension itself is relieved by the stretching of the shortened soft parts and the shortening of those that were stretched. The foot must be retained in the position of correction or in some safe modification of it until these structural changes have had time to take place.

Obviously, retention is the principal element in the treatment of a club-foot. All cases should be watched and most of them will require some degree of retention until the function of walking is well established. At this time a new element comes into the case and the efficiency of the preceding treatment will be severely tested. We have all probably been taught that the proximal is the fixed end of a muscle—that distal parts move upon proximal. This is true of the lower extremity in infancy when the foot is an appendage to the leg. But when the subject stands and walks, this action is reversed. The foot, especially the front portion, becomes the fixed part and the other parts of the body are adjusted to it by the muscles. Almost all the stresses of the body are transmitted to the feet. In walking, one foot and the heel of the other are raised and the whole body with perhaps a heavy burden is lifted and carried upon a few inches of forefoot. The strain upon this tiny base, the muscular force which acts from it, is enormous. At the time of

*Read at an annual meeting of the Montana State Medical Association held at Lewiston, Mont., July 9, 1914.

the performance of their physiological function, normal feet become markedly harder. The resistance which characterizes a club-foot if not overcome increases steadily from birth, but is at this time distinctly augmented. This impending change must be taken into consideration and forestalled by efficient retention from the beginning of treatment. While it is possible to produce a permanent overcorrection by retaining the foot too long, the danger of relapse from releasing it too soon is very much greater. The test is to leave the dressing off for an hour and then note the resistance of the foot to correction. If this is not increased, the experiment may be repeated and the time gradually extended. But whenever the unrestrained foot shows a new resistance to correction the retention must be renewed. A foot well flexed upon the leg can be held so with little force, but as it approaches the right angle position with the leg, the position of use, it is less under control, the deforming tension acts upon it at a mechanical advantage and at the time of use, this tension if it still persists, is increased. Body weight will not diminish the deformity. It will increase it. Feet which seemed super corrected usually walk themselves into excellent shape. For those which prove to have been inefficiently treated radical measures are now necessary and walking will have to be deferred until the feet have been prepared for it. It is not possible to correct very much a foot which is in use.

For both correction and retention, plaster of paris because of its peculiar softening effect is especially serviceable, and when removable apparatus seems inadequate to hold a foot, one has a comfortable feeling of having plaster to fall back upon. The plaster bandage is applied over several layers of sheet wadding bandage; and to turn the foot out, the knee is flexed and the plaster carried well up on the thigh.

The use of plaster means, however, complete immobilization; and, as exercise is advisable as soon as possible and as the foot must eventually assume the position of use, in a range of motion a few degrees each way from a right angle with the leg, some sort of removable appliance and one which will permit controlled motion is necessary. I have found this broad curved band of leather (Figs. 1 and 2) an efficient holder for cases which have been thoroughly corrected. When its ends are brought together, it forms a truncated cone to contain the lower part of the leg and the upturned foot, the heel being at the apex of the cone. The part in contact with the sole is stiffened by a sole plate of brass or sheet iron covered with leather and riveted on. The ends are laced together down the outside of the leg. The sides of the cone are drawn in by a lace passing in mattress-suture fashion through perforations in the leather and transversely across the top of the foot, between it and the leg. The perforations on the outer side are nearer the sole plate than those on the inner so that when the foot is pulled up by the tightening of the lace, the outer side is drawn up higher than the inner and the sole is tilted outward. A piece of felt under the lace protects the skin. Or a tongue may be attached just above the heel, pass forward under the foot between it and the sole plate, turn back over the toes and cover the top of the foot. This is desirable in walking cases. The variations possible with the front and side lacings allow quite a range of adjustment. For small feet I have the ends of the leather, instead of meeting at the side of the leg, overlap under the sole and to the width of the sole plate where they are sewed and the sole plate inserted in the pocket thus formed. This sort is not as adjustable as the other. Any shoemaker can cut the holder from a pattern made by the physician, and the cost is so trifling that several may be made if necessary to obtain a good fit. The foot, apparently cured, should be released experimentally and watchfully, and it is well to use a holder at night to maintain flexion beyond a right angle for several months after the treatment has been otherwise discontinued.

In some cases of club-foot the heel cord is so resistant that the dorsal flexion takes place at the middle of the foot instead of at the ankle and the foot is liable to be flat. This tendency must be watched for early in the case and can generally be prevented by making the flexing pressure at the middle of the sole instead of at the ball of the foot. Most club-feet which are flat when the child begins to walk will arch up after a while, some will require an arched sole plate, and a few will need section of the heel cord. This should not be performed until the foot has had time to correct its own flatness.

OWSLEY BLOCK.

Medicolegal Notes.

Proof of Medical Services Rendered to a Decedent—Books of Account.—In an action for medical services rendered to a deceased person against his estate, it was held that testimony of the plaintiff as to personal transactions with the deceased was prohibited by the New York Code of Civil Procedure, section 829, as to the competency of witnesses. The plaintiff's account books were also held to be inadmissible, in the absence of independent evidence, showing the course of dealing between the parties and the rendering of some service by the plaintiff to the deceased. The plaintiff's inability to produce competent proof was held to be no ground for sustaining a judgment on insufficient and incompetent evidence.—Titus vs. Spencer, New York Appellate Division, 145 N. Y. Supp., 40.

Liability of Local Authorities for Medical Services.—Indiana Burns' Ann. St. 1908, §9741 *et seq.*, providing for the support of the poor, and requiring the overseer of the poor in each township to care for all poor persons, and in cases of necessity to promptly provide medical attendance for the poor not provided for in public institutions, etc., repeals former laws on the subject, and a township is liable for medical attendance rendered a poor person in an emergency without opportunity to communicate with the overseer. A surgeon rendering services under an emergency demanding immediate medical attention is entitled to recover the reasonable value thereof.—Newcomer vs. Jefferson Tp., Indiana Supreme Court, 103 N. E., 843.

Hospitals' Liability for Negligence.—The rule adopted by the Texas courts as to the liability of hospitals, organized to minister to all persons of all creeds, for the negligence of physicians, nurses, and servants, who are said not to be agents of the institution, is that such hospitals are liable only when it appears from all the facts and circumstances that the institutions failed to exercise ordinary care in the selection and retention of such employees. In the application of the rule it is immaterial whether the patient upon whom the injury was inflicted be a beneficiary of the charity of the institution or one who is paying full consideration for his or her care and nursing. In a suit against such a hospital for injuries sustained by the plaintiff's wife, who, after an operation, was placed in a bed in which there was a water bottle so hot that it severely burned her, it was held that the selection of an inexperienced person, whose usual duty was to wash dishes and run errands, to perform the task was sufficient to sustain a finding of the jury that the hospital had not exercised ordinary care in the selection of its servants.—St. Paul's Sanitarium v. Williamson, Texas Civil Appeals, 164 S. W. 36.

PATHOLOGY AND DIAGNOSIS OF PYLEPHLEBITIS.

SEPTIC thrombosis of the portal vein occurs more frequently than is generally recognized. For this reason considerable importance must be attached to the clinical and laboratory study of this subject by H. Schottmüller (*Beiträge zur Klinik der Infektionskrankheiten und zur Immunitätsforschung*, Vol. 3, Nos. 1 and 2). Of course, in tropical countries dysentery is the most prominent cause of portal phlebitis, but in temperate climates the outstanding cause is appendicitis. Less common factors are inflammatory processes in the region of the rectum, abscesses in the spleen with thrombophlebitis of the splenic vein, disease of the biliary passages, and inflammatory processes in the liver with infection of a branch of the portal vein, as may occur with echinococcus.

In a case of appendicitis the indications for speedy operation are usually the danger of peritonitis or of a perityphlitic abscess. Rarely is the menace of a pylephlebitis thought of, although this menace is a real one. A case reported by the author strikingly illustrates this sequence. A nineteen-year-old girl was admitted to the surgical division of the Eppendorfer Krankenhaus with the diagnosis of appendicitis. The following day there was no longer any pain or tenderness in the appendix region and operation was accordingly deferred. But the next day there was a chill and one or more chills were repeated daily thereafter. The possibility of a pyelitis was then thought of. On the fourteenth day of the disease the patient appeared quite ill and presented a slight jaundice, chiefly of the conjunctiva. The sensorium was clear, the heart and lungs were apparently normal, and the abdomen showed nothing of moment except a slight distention, a slight enlargement and tenderness of the liver, and a moderate swelling of the spleen. The leucocyte count was 13,000 and the urine presented no evidence of pyelitis. On account of the wide daily excursions of the temperature and the above findings, the diagnosis was made either of a pylephlebitis or of a cholangitis. But the slight degree of icterus and the history of a recent appendicitis narrowed the diagnosis to that of pylephlebitis. In the fourth week of the disease the temperature was of a more continuous type and there was only one chill. The leucocytes numbered from 20,000 to 70,000 and the polymorphonuclear cells were relatively greatly increased. On the eighteenth day of the disease there appeared peculiar cutaneous changes, particularly in parts of the body exposed to pressure. These changes consisted in the appearance of tender edematous swellings, the size of a walnut, and with a dark red center. Gradually the skin in the affected areas presented a blush-red color, and there were the appearances of a subcutaneous necrosis. After the third week there was a clouding of consciousness which deepened into coma, and death occurred at the end of the fourth week. Bacteriological examination of the blood at different times during the illness showed the presence of Gram-positive bacilli resembling the E. Fraenkel gas bacillus, and fine Gram-negative rods, more delicate than colon bacilli; and at one time there was present the *Streptococcus putridus*. At autopsy there were revealed necrotic foci in the appendix vermiformis, widening and suppuration of the mesenteric veins in the region of the cecum, and widespread thrombosis and suppuration throughout the portal venous system.

The outstanding feature in this case was the occurrence of symptoms of portal phlebitis at almost the very outset of an attack of appendicitis. A second case is reported, however, in a man aged fifty years in whom an appendicitis was entirely masked by the symptoms of an acute gastroenteritis. The appearance of the patient suggested typhoid fever, but a septic temperature, a slight icterus of the conjunctiva, a marked swelling of the left lobe of the liver, and the results of a blood culture which showed the presence of numerous anaerobic bacilli together with colon bacilli, pointed to a portal phlebitis. This diagnosis was confirmed at autopsy.

In addition to the remittent temperature curve the bacteriological findings furnish the most important diagnostic criterion in this condition. Characteristic are the growth in the blood of anaerobic organisms, and the evidences of a mixed infection. The necrotic changes in the skin without the occurrence of suppuration are regarded as quite typical of the presence of anaerobic bacteria.

Schottmüller believes that some cases of septic thrombosis of the portal vein undergo a spontaneous recovery, analogous to the cases of puerperal thrombophlebitis. He also believes that many cases reported in the literature as instances of syphilis of the liver, in which a prolonged intermittent temperature and an enlarged liver had been present, really belonged to the category of pylephlebitis.

BULLET WOUNDS IN WAR.

THE medical and surgical experience gained by the British in the South African war of 1902 cannot fail to be of value in the present campaign. This experience was particularly rich in the treatment of the different types of bullet wounds. W. G. Tottenham Posnett, who had the opportunity of treating 1,000 cases of bullet wounds during the Boer War and the subsequent Zululand rebellion, is entitled to speak with authority on this subject. In the *Lancet*, September 5, 1914, he states that

the bullets at present in use are more pointed than those used in South Africa and have a considerably lower trajectory. It remains to be seen whether this will inflict a wound different from that seen during the Anglo-Boer campaign. The modern rifle bullet has great penetrating power at the middle distance, from 300 to 900 yards range, and wounds, even where bones are implicated, received at this distance are of a more penetrative character than those received at a closer or longer range. The smashing power of a bullet up to 300 yards is considerable, producing great comminution of bone. At 900 yards or over the smashing power of the bullet is again considerable, inflicting bone injuries of the most serious magnitude. The high velocity nickel-covered bullet is more or less aseptic. As a rule, the wounds of soft tissues are not of a serious nature, but if in its flight a bullet happens to hit a hard object and ricochets, the wound inflicted may be a large lacerated one. When a bullet strikes a bone in its course through the body or limb, if the wound be received at the middle distance, the bullet may pass clean through the bone without doing any serious damage, but if the wound be received at close range or over 900 yards, bones struck are shattered as a rule into many fragments and yet the exit wound may be of the same size as that of entrance.

A clean wound of the abdominal viscera in most cases heals rapidly and requires very little treatment; multiple abdominal wounds may demand operation but are best treated expectantly for a few days until symptoms of local trouble arise. There is often great initial shock when a bullet wound is received, particularly if the soldier goes into battle in a hungry condition and is more or less tired by marching. On the other hand, an empty stomach is frequently the salvation of a soldier who has been shot in the abdomen; a wound of the stomach or intestines seems to close rapidly without any trouble, provided there has not been any leakage of gastric or intestinal contents. If leakage does take place a localized peritonitis demanding laparotomy may be expected. Wounds of the bladder usually require a suprapubic cystotomy. Wounds of the soft parts are usually accompanied by local shock. The great velocity of the bullet shakes up the tissues for a considerable distance around the wound; there results a feeling of stiffness in the part for several days and there may be more or less neuralgic pain in the vicinity of the wound for a considerable time. Tissues in this condition are not favorable for operative attack. Posnett believes it is better, if possible, to wait a few days for the local shock to pass off before attempting operation.

CAUSES OF SUDDEN DEATH IN THE WATER.

None of the reasons heretofore adduced to explain sudden death in swimmers is completely satisfactory. One of these has never received the attention which it merits. In 1881 von Troltsch asserted that in a number of such accidents death was due to vestibular irritation as a result of the penetration of cold water into the ear. To offset this view, however, is the common observation that children with large perforations of the drum head swim and dive with impunity, and this despite the fact that otitis from bathing is by no means rare, and that old otitides are lighted up by the same exposure.

At a meeting of the Berlin Otological Society held last spring (*Berliner klinische Wochenschrift*, August 10), Güttich revived the view that sudden death can follow vestibular irritation in swimmers with perforated ear drums. In those under water caloric mystagmus is set up, and this is followed by Bárány's muscle reaction which renders the patient helpless—he can neither swim nor reach the surface. He makes motions, but there is complete loss of orientation. A second rotary reaction now occurs, the swimmer turning on his own axis. If these reactions are for any reason in abeyance, the patient may still suffer fatal collapse accompanied by vomiting.

While this accident menaces chiefly those with perforated ear drums, it could readily, in divers, follow an acute traumatic perforation in the water and perhaps occur exceptionally with intact drum head. Sudden helplessness in the water is better explained as a vestibular phenomenon than by the view of total or subtotal tonic cramps, affecting the respiratory muscles. However, if the patient first becomes helpless when his head is above water the vestibular explanation will hardly answer.

Dental Alopecia.

Owing to the common embryonal origin of the cutaneous appendages and the teeth, it does not surprise us to find them involved together in congenital malformations. The dentition may be defective in congenital absence of hair, and when the latter is very redundant, as in certain cases of familial hypertrichosis (dogfaced men), there may be very notable dental defects suggesting compensation. Attention has often been called to the coincidence of early baldness and early caries, and some years ago an attempt was made to isolate a distinct affection of the two systems under the name of Jacquet's disease. At a discussion last June on hair anomalies before the biological section of the Aerztlicher Verein of Hamburg (*Münchener medizinische Wochenschrift*, July 28) the condition "alopécie dentaire" was mentioned by two of the members. Plaut as a result of his own experience was inclined to hold the teeth responsible for the production of certain cases of alopecia areata. Very convincing was the fact that when springs were worn to correct the position of the teeth, baldness in spots often appeared, the hair growing in after the removal of the spring.

Postpartum Hemorrhage and Puerperal Infection.

The relationship between the acute anemia which follows postpartum hemorrhage and child bed fever seems never to have received due consideration. In the large maternities the incidence of both conditions has been greatly diminished. When hemorrhage does occur, as from retained placenta, manual extraction possesses possibilities of infection which do not depend on the blood loss. At the

annual meeting of the Medical Section of the Schlesische Gesellschaft für vaterlandische Cultur, Breslau (*Berliner klinische Wochenschrift*, August 3), Bondy made a statistical report on this important subject. In a series of 9,000 labors he found 120 cases in which the loss of blood exceeded 1,000 c.c. Of this number 24, or one-fifth, were associated with manual detachment of the placenta, and there were 10 cases of the latter uncomplicated by hemorrhage. An important distinction exists between spontaneous and assisted labor. In the former losses of blood even up to 1,200 c.c. were associated with but a slight increase of morbidity, but in losses beyond this limit a considerable increase resulted. Morbidity in instrumental delivery was notably higher than in spontaneous labor, first in losses up to 1,200 c.c., and second, proportionally, in greater losses. Manual detachment with great loss of blood causes a higher morbidity than the same with smaller losses. In general, notable blood loss is an indirect factor in puerperal morbidity.

News of the Week.

Postponed on Account of the War.—The International Congress of Hygiene, which was to have met in Philadelphia the last week in September was not held, as the European delegates were unable to attend. The meeting of the American Open Air Association which was to have taken place at the same time was also postponed.

Pellagra a Notifiable Disease.—The Greenville, S. C., Board of Health has added malaria and pellagra to the list of diseases all cases of which must be reported by the attending physician.

American Public Health Association.—The forty-second annual meeting of this Association will be held in Jacksonville, Fla., on November 30 to December 5, 1914.

The Southern Health Exhibition will be held in Jacksonville, Florida, November 27th, to December 6th, 1914, in connection with the Forty-Second Annual Meeting of the American Public Health Association. At this exhibition will be attractively shown material covering a wide range of subjects pertaining to health conservation which will appeal, not only to the sanitarians, but to the public at large. The exhibits will comprise the work of State and municipal boards of health and of private and semi-public organizations throughout the entire South, as well as the work of the United States Public Health Service. Almost every phase of health conservation work will be covered, such as rural sanitation, typhoid, hookworm, tuberculosis, pellagra, malaria, school construction and medical inspection, infant and child hygiene, midwifery, vital statistics, milk and water supply, food and drug inspection, habit-forming drugs, insect carriage of disease, fly eradication, plague prevention and rat extermination, and laboratory work, together with modern sanitary apparatus of every description.

Faculty Changes at Syracuse.—Dr. Oliver W. H. Mitchell, formerly of the University of Missouri, has been appointed professor of bacteriology at the College of Medicine of Syracuse University, and Mr. Ralph R. Simmons has been made his assistant. Dr. Edward D. Clark has been made assistant to Dr. F. M. Mead, assistant professor of preventive medicine, and Dr. Howard L. Van Winkle has been appointed instructor in this department. Several men have been added to the teaching force in the new dispensary, opened last June, and instructions will be given by them to seniors and juniors in the various departments.

The Health of New York.—The death rate in New York City for the first thirty-eight weeks of this year was 13.94 per 1000 as compared with a rate of 14.20 for the corresponding period of 1913. The mortality for the last quarter of the year, as a rule, is considerably lower than that of the other quarters, and the probabilities are strongly in favor of a death rate for the year considerably below 14 per 1,000.

American Doctors to Paris.—Seven physicians sailed from New York on Saturday for service on the staff of the American Ambulance Hospital in Paris, at the head of which is Dr. Joseph A. Blake of this city. They were Drs. Richard Derby, J. P. Hoguet, A. H. Dugdale, Mercer Blancard, Corry, Benjamin Joblons, and Lester Rogers.

Southwestern Iowa Medical Association.—The annual meeting of this society was held in Corning on September 10. The following officers were elected: *President*, Dr. J. F. Herrick of Ottumwa; *Vice-President*, Dr. George Mogridge of Glenwood; *Secretary and Treasurer*, Dr. Enos Mitchell of Weldon. The next meeting will be held in Glenwood.

The American Roentgen Ray Society.—At the fifteenth annual meeting of this society, held in Cleveland, Ohio, during the second week in September, the following officers were elected: *President*, Dr. Alfred L. Gray of Richmond, Va.; *Vice-Presidents*, Drs. A. Howard Pine of Montreal and D. R. Bowen of Philadelphia; *Secretary*, Dr. W. F. Manger of Philadelphia; *Treasurer*, Dr. Leonard Reu of Buffalo; *Chairman of the Executive Committee*, Dr. George C. Johnston of Pittsburgh.

Trichiniasis.—The Health Commissioner of New York calls attention to the alleged increased prevalence of trichiniasis in the city. A number of cases have been reported to the department during the past month. While the disease is not one of those the notification of which is required by the sanitary code, the department will welcome further voluntary reports of cases.

Personal.—Dr. S. Adolphus Knopf of this city has been commissioned first lieutenant Medical Reserve Corps, U. S. Army.

Dr. Laura Hunt has been elected professor of otology in the Woman's Medical College of Pennsylvania in succession to the late Dr. Emma Musson.

Dr. Edward Livingston Hunt of this city has removed to 41 East Sixty-third street.

Dr. Thomas H. A. Stiles of Scranton, Pa., has been appointed by State Commissioner of Health Dr. Samuel G. Dixon medical director of the new sanatorium for tuberculosis at Hamburg, Pa.

Dr. Arthur A. Stevens has been appointed visiting physician to the Philadelphia General Hospital in succession to Dr. Augustus A. Eshner, resigned.

Roof-Garden for Hospital.—The new roof-garden for the Allentown (Pa.) Hospital was opened on September 23. It will accommodate 20 patients, and it is intended for those suffering from pulmonary tuberculosis, pneumonia, and typhoid fever.

Charitable Bequest.—By the will of the late Francis Heyl of Philadelphia the sum of $500 is bequeathed to the Pennsylvania Hospital for the Insane.

Adenoids and Tonsil Operations at Children's Clinics.—The Department of Health maintains

four clinics for the operative treatment of adenoids and enlarged tonsils in school children whose parents are unable to afford the service of a private physician. Operations are all done now under anesthesia, and the children are kept at the clinics until the following day. Heretofore the operations were done only three days a week, but the large number of patients applying for treatment has necessitated daily operations. During the week ending September 5, 1914, 137 nose and throat operations were performed at this children's clinic. The average number of operations performed for the three weeks preceding the inauguration of daily operations was 77.

The American Association for Study and Prevention of Infant Mortality.—The fifth annual meeting of this association will be held in Boston, November 12-14, under the presidency of Dr. J. Whitridge Williams of Baltimore. The program will include sessions arranged by the committees on nursing and social work, pediatrics, vital and social statistics, obstetrics, and public school education. The subjects to be discussed will include: "Prenatal Care," "The Need for Increased and Improved Maternity Hospital Service," "Institutional Mortality," and "Continuation Schools of Home-Making." The session on nursing and social work and the joint session on pediatrics and vital social statistics will be held at the Harvard Medical School. All other sessions will be held at the Copley Plaza Hotel. Special clinics will be held on the opening day of the meeting at the Harvard Medical School and elsewhere, the exact time and place to be announced later. An exhibit will be held in connection with the meeting. The chairman of the committee on local arrangements is Dr. Hugh Cabot, 87 Marlborough street, Boston, Mass. Further information or circulars in regard to the work of the association can be secured from the executive secretary, Gertrude B. Knipp, 1211 Cathedral street, Baltimore, Md.

Obituary Notes.—Dr. JOHN MCGRAW WOODBURY of this city died at his country home, Southampton, L. I., of pernicious anemia on September 24. He was born in this city in 1856 and was graduated from the Bellevue Hospital Medical College in 1881. He served as surgeon with rank of major on the staff of Gen. James H. Wilson in the Spanish-American War and was appointed Medical Director General of Ponce, Porto Rico, when that island came under United States control. His successful work there showed him to be possessed of much sanitary skill and administrative interest and led to his appointment as street cleaning commissioner of New York City by Mayor Low in 1902. He was reappointed by Mayor McClellan, but resigned later when he was directed to remove a competent subordinate to open the way to a political appointment.

Dr. JAMES B. WARE died at Bridgeton, N. J., on September 8 at the age of 83 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1854.

Dr. JOSEPH H. LOPEZ died at Philadelphia on September 15 at the age of 69 years. He was graduated from Jefferson Medical College in the class of 1876. He was medical director and trustee of the Charity Hospital.

Dr. JOHN LANSON ADAMS of New York was killed by a fall from a window of his residence on September 25. We was born in Westport, Conn., August 9, 1860, and was a graduate of the College of Physicians and Surgeons in this city in 1886. He was attending surgeon at the New York Eye and Ear Infirmary, consulting ophthalmologist to the Lying-In Hospital and the Manhattan State Hospital, and director of the West Side German Dispensary and of St. Bartholomew's Clinic. He was president of the New York Clinical School of Medicine.

Dr. ARCHIBALD T. DAVISON died at his home in Cambridge, Mass., on September 19, after a long illness, in his 88th year. He was born in Nova Scotia and was a graduate of the Harvard Medical School in the class of 1871. He practised for many years in South Boston and afterward in Dorchester.

Dr. JAMES KOSSUTH KING, 64 years old, died at his home at Glen Springs, Watkins, N. Y., on September 20. He was born in Troy, N. Y., and was graduated from the College of Physicians and Surgeons in this city in 1877. Upon returning to this country after a long course of study abroad, he practised at the Clifton Springs Sanatorium until 1890, when he became one of the founders of the Glen Springs Sanatorium, of which he was the medical director for twenty years.

Dr. MORRIS LONGSTRETH, late of Cambridge, Mass., and formerly of Philadelphia, died at Barcelona, Spain, on September 19 at the age of 68 years. He was graduated from Jefferson Medical College of Philadelphia in the class of 1869, and he was later professor of pathology in that institution. He was also at one time physician to the Pennsylvania Hospital and coroner's physician for the city of Philadelphia. He was a member of the Medical Society of the State of Pennsylvania and a fellow of the American Medical Association. He was a non-resident fellow of the College of Physicians of Philadelphia and a member of the Pathological Society of Philadelphia and of the Association of American Physicians.

Dr. MAHLON H. BEARY died at Allentown, Pa., on September 18 at the age of 74 years. He was graduated from the College of Physicians and Surgeons of Keokuk, Iowa, in the class of 1880. He was a veteran of the Civil War, having served with the 128th Pennsylvania Volunteers.

Correspondence.

PARIS IN WAR TIME.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Among all the months of the year in Paris September is the most beautiful; the actual summer heat is gone, there is a bracing freshness in the air at early morn, and yet the city's great wealth of trees, grass, and flowers is still at its height. Truly it is lovely here just now, and you can safely take my word for the above statement—this is my thirtieth month of September in Paris!

And yet—there are certain features about the town this autumn that are not as they usually are. Have you ever arrived absurdly early at the opera, when the iron curtain was still lowered, the orchestra empty of its musicians, and not more than fifty spectators were scattered about the house? That is the way Paris looks now; the beautiful *cadre* is all here, but the "filling-up" is almost entirely lacking; and those of us who know what the opera-house looks like in the midst of a gala performance are overcome with a sadness unspeakable as we shudder at the thought of this criminal.

this monstrous war that is going on even within our faint hearing, and that forms such a revolting contrast to all the loveliness and quiet spread out before our eyes.

The point that first strikes you now in Paris is the emptiness of the streets; vehicular traffic is nearly entirely gone, and pedestrians are not many. All that crush of noisy motor omnibuses—vanished to the war; the endless taxis standing in sheds for lack of drivers; an occasional tram comes along, filled to overflowing, run by a man too old to serve, and conductored by a woman, wife of an employee with the army; and the city pedestrian, who usually hugs his sidewalk and refuge with an ever cautious eye, has now become as careless as his worst country cousin, and saunters heedlessly along in the middle of the street, buried in his newspaper, just as though such a thing as a reckless taxi driver had never existed.

The military note predominates, naturally; men in uniform on every side, and quantities of others with *brassards* on their arm, to indicate to which public service they belong. A man of military age without some distinguishing mark of this sort is liable to be stopped and have his papers called for. We foreigners have all to go about with a police document authorizing our residence in the *Camp retranché de Paris*. The British Tommy lends a strange note to the streets. Serious, clean-shaven, and with neat and serviceable khaki uniform, he certainly is well worth a look; the French soldier may be remarkable in many ways, but I need not tell most of you what he looks like! Profiting by the absence of other traffic the motors on military errands fly along at a pace that must make the Prefect shudder; the ordinary sergeant-de-ville doesn't even see them; he is far too busy discussing the latest rumor with some pal in uniform to bother about such little details as that.

Another feature that makes itself strangely felt about life in Paris just now is the unwonted, almost uncanny silence of the town during the day—not to speak of the night. In place of the never ceasing, muffled roar that has become so intolerable of late years since the introduction of the explosion-propelled vehicle, there has settled down on us the calm of a small, provincial, bourgeois chef-lieu-de-canton. A man in one of the papers summed the situation up very neatly in a few words: "Why," wrote he, "you can actually hear the church bells ring now, something I haven't experienced for years." Another one affirmed that he had heard roosters crow at dawn; but he was evidently carried away by his enthusiasm. This silence has been further intensified by a recent regulation putting a stop to the crying out by newsboys of the special editions of the papers—a very wise measure, as it served no purpose save to unnerve and exasperate the public, who wasted much money and received no news.

For a few days last week we had a ripple of excitement, and quite a noise, owing to the visit of German aeroplanes over the city and the promiscuous firing at them that went on from the various military posts. These airmen appeared several days in succession, dropped bombs indiscriminately among the civilian population, and then returned. These exploits—a particularly dastardly performance, as the airmen were in perfect safety, while their total victims were two elderly women—have now stopped. It was mere cowardly bravado, as such reconnaissances could have no possible military value.

But if the aspect of town by day is surprising, the look it assumes by night is positively extraordinary. Paris is essentially a *ville de nuit*, and I need hardly remind any one familiar with the city of the dazzling lights and unceasing movement on the boulevards and other frequented parts of town at night. But what do we see at present? Whole sections of the capital have no street lamps alight at all; thus the Avenue du Bois in its entire length, together with the streets running from it on either side, is left in absolute darkness at night. Even in the center of town, the rue de la Paix, Place Vendôme and rue Castiglione are practically dark. Other main thoroughfares, such as the Avenue de l'Opera, have a row of lights burning down the central line, but nothing on the sidewalks. All the gay electric advertisements are gone. All of the tables and chairs out on the sidewalks in front of the cafés are taken in by 8.30 P. M. and the establishments closed to all intents and purposes; just try to picture to yourself, O cosmopolitan *fêtard*, the café de la Paix, familiarly known as the center of the Universe, closed at 8.30 P. M.! You might as well be in a Maine prohibition village with a Moody and Sankey revival going on. All of one's favorite little restaurants around the corner—closed! I tried several in succession the other evening, with unbroken unsuccess, and finally had to fall back on a common Brasserie on the Boulevards. The Opera and all the theaters closed also—naturally. Along the almost silent thoroughfares moves an orderly, serious stream of people, many of them undoubtedly, like ourselves, there to see how the town looks under these impressive circumstances; while over the center of the way rush the dust-covered military motors containing French and English staff officers from the fighting line, now only a few miles from Paris—for the Germans have come as close as Chantilly, to the North, and this side of Lagny to the East—too near for comfort. Overhead flash and cross each other the unceasing searchlights that move slowly and inquiringly over their prescribed sectors—though just what they propose to accomplish is beyond my intellectual horizon; what Zeppelin would want to come to Paris at night, and if it chose to, what would the searchlight do about it! But in spite of entire quarters of town being steeped in utter darkness, the criminality of Paris is reduced to a remarkable minimum; a large portion of that amiable Parisian product, the *Apache-soutcneur*, is undoubtedly under arms, and the rest find the profession rather risky for the moment. Paris, being under military law, anyone caught in crime would have but very scanty shrift.

Life is particularly monotonous just now. The French government's policy is to tell the people nothing—it saves trouble. We are treated like babes-in-arms. Were it not for the London papers that manage to get through with unaccountable delays, we should know absolutely nothing. The fact is, we have become mere readers of newspapers; it is an actual impossibility to settle down to any kind of connected or serious reading. One peruses the first morning papers, and then starts out to see what others are to be bought, until such a time as the afternoon sheets begin to come out. Each one will contain a morsel or two, letters from men at the front in particular; and by putting all these fragments together we try and imagine what is taking place. About the only authoritative account of events we have is the weekly military summary in the *London Times*.

Material existence is tolerable. Prices have not risen much, and the greater part of the ordinary commodities are to be obtained. Gas is limited; coal and wood can be bought, but delivery is very slow, hardly under a week; salt, canned milk, dried vegetables and fruit were all exhausted recently. If this is the case already, in midsummer, and the war only begun, what will it be later on, in winter, and with the possibility of investment! The military governor has been taking a census of the people remaining after the huge emptying of the town that took place two weeks ago when the German initial rush was at its maximum, and we are still a good two millions; this census was for the purpose of establishing our ration-cards, and to the declaration papers of each family was affixed the signature of the party that was to draw the daily allowance from the authorities. This gave me a chill down the spine, as I had visions of horse-flesh and black bread; fortunately I had laid in a large provision of Spratt's biscuit for my dog, and I am assured that they are not half bad eating for human beings, when other articles of diet run short! An elderly lady who went through the siege of 1870 tells me that during the last few days of that period she practically lived off of cod liver oil! Curiously enough, during that war I was a boy at school in Germany on the Rhine, and I recollect perfectly visiting the large camp of French prisoners near Coblentz, and seeing others pass through Bonn by the trainload. C. K. Austin, M.D.

OUR BERLIN LETTER.

(From Our Regular Correspondent.)

X-RAY TREATMENT OF CANCER—SUPERIORITY OVER TREATMENT BY MEANS OF RADIOACTIVE CHEMICALS—GREATER PENETRABILITY OF THE X-RAYS AND LESS HARMFUL EFFECTS ON THE TISSUES—TECHNIQUE OF X-RADIATION AND EFFICACY IN UTERINE AND IN MAMMARY CANCER—FAILURE IN OVARIAN CARCINOMA—GERMAN CENTRAL ANTITUBERCULOSIS COMMITTEE—PREVENTION OF INFANTILE TUBERCULOSIS—MUNICIPAL HOUSE INSPECTION IN THE CAMPAIGN AGAINST TUBERCULOSIS—AFTER-CARE OF PATIENTS DISCHARGED FROM TUBERCULOSIS SANATORIA—THE BERLIN HOME FOR CRIPPLES.

Berlin, August 15, 1914.

The cure of deep-seated carcinoma by means of *x*-ray applications to the surface of the body was the subject of one of the most important papers read during the past summer. This subject was presented before the Hufeland Society by Bumm and Warnekros. According to their experience the penetrating power of radioactive substances extends only to the depth of two to three centimeters. If a superficial cancer is treated by means of these substances it may be eradicated, but its metastases are not affected. The results in this respect are the same even if larger doses of the radioactive substances are used or if their action is prolonged. On the other hand the bad effects of this exposure in the production of suppuration and necrosis are thereby increased. In contradistinction to the above substances the *x*-ray tubes may be made to exert their influence upon greater depths and their harmful effects may be more easily avoided. Of the many experiments performed by the authors the following may be mentioned: In the vaginal fornix of carcinomatous women there were placed the sensitive strips of the Kienböck apparatus, and these were subjected to radiation from the outside of the abdomen. The strips turned brown in ten minutes, whereas they did not change when subjected to the action of 200 milligrams of mesothorium that had been placed on the abdomen. Only at the end of eleven hours was a slight change perceived in the strips, while the skin of the abdomen later presented a burn of the second degree. Besides, the measurements made by a series of electrical and chemical apparatuses showed unmistakably the great superiority of the *x*-ray tubes over the radioactive substances. It has been maintained that between the *x*-rays and the radioactive substances there is this important difference: the *x*-rays have a greater penetrability and have a greater elective affinity for the carcinoma cells. These opinions have not been substantiated. In fact, the clinical experience of the authors has shown that in the treatment of cancer only those rays are effective that actually reach the growth. Whereas in the case of superficial carcinoma 3-500 X doses of the *x*-rays are necessary for the eradication of the growth, the same dose is necessary if the growth is a deep-seated one. The same is true if the growth is up to ten centimeters deep. Since at this depth one-seventh of the superficial rays are effective, there must be employed rays having a seventeenfold strength; in other words, a strength of 3-500 X radiations. This is possible only with tubes having very hard rays, that are held at a considerable distance from the skin, and that are moved so as to emit the rays from different positions. The authors reported a series of cases of cancer of the uterus that as a whole were most favorably influenced by the *x*-rays. An example of these cases was the following: In a woman, aged 41 years, the portio vaginalis was surrounded by an everted growing carcinoma the size of a small saucer. During a period of thirty days the patient received on fourteen different cutaneous areas twenty exposures to the *x*-rays. In the course of this treatment the cervix returned to its normal form and the hemorrhage and discharge ceased.

In addition, fourteen cases of mammary carcinoma were treated by means of the *x*-rays. In twelve of these cases there were extensive inoperable growths with glandular involvement. With the exception of one case, a cure was effected even to the extent of the disappearance of the glandular metastases and the infiltrations. In one case there resulted from the irradiation a dissemination of cancerous nodules upon the integument, and the patient succumbed. A most extraordinarily good result was obtained by the authors in a case of extensive cancer of the left lung. Complete cure was obtained in this instance in six weeks. An *x*-ray picture showed a disappearance of the previously obtained shadow.

This method has as yet failed in the case of ovarian carcinoma, inasmuch as in this instance the growth attains a very great size and gives rise to early metastatic formation. The sole harmful effect in this method of radiation has been the irritation of the skin and the blistering, which disappears in three or four weeks and does not lead to deep necroses.

The meeting recently held of the German Central Antituberculosis Committee was the occasion for the presentation of a number of interesting papers. The first of these was the prophylaxis of infantile tuberculosis. The symposium was opened by Langstein, of Berlin, who stated that infants in

the first and second years are subjected to the danger of tuberculosis to an extent eight or nine times as much as adults. The best preventive is the removal of the child from the tuberculous milieu. This is, of course, but seldom possible. It has been shown by extensive investigation that children of tuberculous parents that have received institutional care, and that, therefore, live according to hygienic rules, are less apt to become tuberculous than children of tuberculous parents that have not had the advantage of such care. Measures designed to increase the child's resistance to tuberculous infection, such as the administration of antibodies through the mother's milk, have not been sufficiently tested. The best remedy as yet available is early isolation and the instruction of the parents.

That municipal home inspection can accomplish a good deal in the fight against tuberculosis was the keynote of a paper read by Seydel and Goldstein, of Charlottenburg. It was shown that the homes of consumptives are more densely crowded than those of other people. The more the disease has progressed the greater the overcrowding becomes, inasmuch as the diminished family income necessitates the taking in of boarders. The efficiency of municipal tenement house departments would, therefore, consist in the discovery and the prevention of such conditions. Home-nursing could be improved by the periodical visits of trained nurses, who would instruct the mistress of the home and who would provide for the care of the children. The cooperation of such home supervision and tuberculosis institutions can be readily brought about.

The committee meeting of the German Central Committee followed the general meeting. The new secretary read the annual report in which he stated that there are now in Germany 158 sanatoria for adults, with 15,877 beds, 32 sanatoria for children, and 23 sanatoria for cases of patients with bone and joint tuberculosis. The most important theme that came up for discussion was the after-care of patients discharged from sanatoria. Roepke stated that this care should depend upon the condition of the discharged patient and upon the results of the treatment which he has received. A change in occupation is necessary only when the previous occupation has favored the development of tuberculosis. However, it has not been proved that the good effects produced in any individual by sanatorium treatment are compromised by the later effects of occupation and milieu. Special supervision is required in the case of the female sex. Young girls who have been clinically cured should not enter into matrimony for at least two years. In the case of married women conception should be advised against for the same period. There are many valid reasons for the artificial interruption of pregnancy in this class of patients. That everyone who has had the benefit of sanatorium treatment should be excused from military service would be, on account of the hygienic value of military service, a mistake. The proposal to send the consumptives to the German colonies in Africa cannot be entertained. However, there is a great deal in favor of the recommendation that the patients discharged from sanatoria should be sent to work on farms or in some other healthful occupation in the country.

In the vicinity of Grünewald there has been erected an institution of somewhat novel type, the new Berlin Home for Cripples, the existence of which, under the initiative of the orthopedic surgeon, Biesalski, and a large number of other philanthropic individuals, has been rendered possible. The main building, erected in the form of a horseshoe, contains sleeping-rooms for 300 children, operating and dressing rooms, and a school. The last has three classes, an additional class for defective children, and two classes for advanced instruction. Besides, in the main building there are workshops for clay-modeling and orthopedic apparatus for the manual training of the patients, and also accommodations for the nursing staff. Of the other buildings there is an administration building and a disinfecting plant. In spite of the fact that the entire institution has been built in a handsome style and has been fitted out so as to serve every need of cripples, it has been possible to confine the expenditure to 5,000 marks per bed. This economy has been rendered possible by the free donation of the land and the gratuitous labors of the architect and others.

THE ARMY IN TROPICAL MEXICO.

(From Our Vera Cruz Correspondent.)

THE sanitary and medical problems which the Medical Department with the Expeditionary Forces of the United States Army in tropical Mexico is called upon to solve, are vastly different from those confronting the medical officers in home territory. Following the bombardment of the city of Vera Cruz by the United States Navy, all public offices, including the police and public health departments, were deserted, and the demoralization of the departments intrusted with public safety and welfare followed as a matter of course. When on April 29 (eight days after the first bombardment which commenced on April 21, 1914, and lasted about two days) the soldiers relieved the Navy from shore duty, they were confronted with the task of policing up a sadly neglected Mexican city. On account of the carelessness of the native inhabitants regarding person and habits, the work of restoring order and cleaning up the town was attended with certain difficulties. True enough, the dead had been cremated and buried, but the city waste and débris of every description that had been accumulating during the days of fighting, were not yet cleared away, and this state of conditions needed immediate attention. The Navy, which was primarily charged with the restoration of peace and safety, did its work, and did it well, but this duty exacted the time of the landing parties to such an extent as to leave no opportunity for the institution of civic improvements.

The news of the American occupation of Vera Cruz brought a great influx of people into the city from every part of the perturbed republic, and with the demoralized conditions existing throughout the country and no quarantine regulations in force, it was not surprising to discover that smallpox made its appearance in the occupied territory. The municipal water supply was inadequate, the working capacity of the filter beds had to be overtaxed to meet the increased needs of the larger population, resulting in a temporary scarcity and a poor quality of potable water. With only one ice plant in the city, which was almost totally disabled by the American shells during the second day's engagement, and without fresh food articles from the adjacent country on the market (their importation into the city being prevented by the retreating Mexican troops encamped in the vicinity and attempting to establish a food blockade from the interior), it can be

readily seen that means had to be devised at once for the proper care of the troops and for the relief of the citizens. Prompt action was taken by the Army authorities; a public health department was established with Major Theodore C. Lyster, Medical Corps, in charge, assisted by an able staff of officers of the Medical Corps of the Army and of the United States Public Health Service. As a result of their activity, supported by the efforts of the various other departments established in response to public necessity, the impending food and water famine was averted, general sanitation was greatly improved, and the threatening epidemics were soon under control. The various army and city health organizations are under the immediate supervision of the Chief Surgeon of the Expeditionary Forces, and by his instructions are regulated the work of the army surgeons and the activities of the health office.

Malaria, gastrointestinal disorders, tuberculosis, smallpox, cerebrospinal meningitis, typhus fever, and yellow fever are the diseases, their prevalence in the order named, to be feared by our troops in Mexico. The number of inhabitants of the city of Vera Cruz approximates the forty thousand mark. The rainy season commences in June and ends with October, averaging a monthly rainfall of eleven inches during this period. The topography of the country is not well adapted to natural drainage, and this unfortunate lay of the land permits the formation of pools of stagnant water which serve as breeding places for mosquitos, and which during the frequent rains of the present season cannot be effectively drained, notwithstanding the extensive ditching done by the Public Health Department for the purpose of abating the nuisance. Mosquitos are numerous everywhere but they especially abound in the suburbs where the outposts of the Army are stationed, and with human carriers and infected anopheles continuously present, malaria is very apt to be the most formidable disease menacing the health of our army in Mexico. The number of registered deaths in the city of Vera Cruz averages about two thousand annually. For 13 per cent. of this number malaria is estimated to be the contributory cause among the native population. Though the death rate from this disease is undoubtedly very high, there is some question as to the accuracy of the figures compiled by the local medical men, who do not appear to be very exacting workers, and that their statistics are not based on strictly scientific principles, is evidenced by the fact that previous to the arrival of the United States troops there was not a microscope in the city. It is impossible without the aid of a microscope to determine conclusively the presence and identity of plasmodium in the blood.

Foreseeing that malaria promised to be the greatest scourge to the health of the soldiers on Mexican soil, prophylactic measures were instituted promptly after arriving in Vera Cruz, even before the troops had left the ships. A prophylactic dose of six grains of quinine sulphate is given daily, the men are required to sleep under mosquito bars at night, and when necessary, to wear headnets and gloves for protection against mosquito bites. Soldiers suspected of suffering from malarial fever are promptly sent to the hospital; here they are placed under mosquito bar in a mosquito proof ward, and all precautions taken to prevent the dissemination of infection. The public health department cooperates with the army in the work of prevention by draining the localities that would afford breeding places for mosquitos, and by covering stagnant water with crude oil, where the former means are of no avail. Notwithstanding all sanitary precautions, there have been under treatment at the army hospital up to and including July 10, 1914, thirty-five cases of malaria, one quartan, five estivoautumnal, and twenty-nine tertian infections among the approximately four thousand soldiers stationed here.

Diagnosis of malaria is never made and no quinine medication is given until the parasite is found in the blood and the identity of the disease thereby conclusively established. In most cases plasmodia have been found in the blood upon first microscopic examination, while in others it has taken as long as a week before the cause of the disease, exhibiting malarial symptoms, was discovered. There were instances when only a single ring indicated the presence of malarial parasites. The difficulty encountered in finding the parasites in the blood of the patient can evidently be attributed to the quinine taken for prophylaxis, and for this reason it sometimes becomes necessary to keep the patient under observation without specific treatment for a period of time, until the drug has been eliminated from his system, in order to avoid a haphazard diagnosis.

Up to this date the treatment, as carried out at the field hospital, has proven satisfactory and effective. Immediately upon admission to hospital the patient is put to bed, and a physical examination is made for the elimination of other diseases from which he might be suffering. Blood smears are taken and sent to the field laboratory maintained in connection with the other medical and health institutions, and which is located in the hospital building; here the slides are at once examined under the microscope and a report made of the findings. Cold sponge baths (repeated every three hours if need be) are given if the temperature of the patient ranges above 103° F.; calomel at bedtime on the day of admission, followed by magnesium sulphate next morning, and symptomatic treatment is begun and continued until the diagnosis is confirmed; meanwhile the patient is kept on liquid diet. When malaria is found specific treatment, consisting of ten grains of quinine sulphate in liquid form every four hours, is commenced, regardless if the patient has fever or a chill, as the medication is not intended to relieve or shorten the chill but to prevent a subsequent attack, for which purpose quinine in its various chemical forms has proven of unequaled benefit. All cases, including the five of malignant type, under care at the army hospital, have readily responded to the described method of treatment. The patient is given regular diet as soon as the fever subsides and his condition warrants it, generally in a day or two after the first administration of quinine. The amount of quinine is reduced after the temperature has remained normal for about a week, and—as is often the case—the patient begins to complain of tinnitus. When after a week's treatment the temperature does not show any variations above normal, and the physical condition of the patient is satisfactory, he is sent back to his organization for duty, but as a precautionary measure to prevent the occurrence of a relapse, quinine treatment is continued for two or three months, or for longer periods, according to the benign or malignant nature of the case. Quinine in limited doses is given for this purpose twice

a week. Should it become necessary to cinchonize the patient more rapidly than is possible with the present treatment, the intravenous method will be resorted to by injecting about twenty-two grains of some soluble salt of quinine in normal saline solution, repeating the dose as may become necessary. The intramuscular method of injection is not considered with favor by the army surgeons in Vera Cruz, on account of its being painful, the site of injection prone to suppuration, and the absorption slow and uncertain.

1. Treatment of Hemoptysis in Pulmonary Tuberculosis.—N. B. Burns points out that the indications call for absolute rest; the immediate lowering of the blood pressure; the determination of blood to parts of the body other than the lungs by means of the application of cold to the thorax; purgation of the intestinal tract; and the positive assurance to the patient that he is in no danger. Morphine is given with great reluctance and only in hopelessly advanced cases, where the sole indication is to preclude all possible suffering. When the hemorrhage is so extensive that the blood rushes into the bronchial passages of the well lung, causing dyspnea and cyanosis, it is best to turn the patient on his side with his head over the edge of the bed, allowing gravity to exert its influence in withholding the blood in the lung the worse diseased. Sodium nitrite and calcium sulphide each in one grain doses may be administered to the patient at three- to four-hour intervals for from twenty-four to forty-eight hours. Subsidence of streaking, as well as severe headache, call for the discontinuance of the sodium nitrite. The author usually gives two doses of one ounce each of magnesium sulphate, one soon after the initial attack, and another on the second day.

3. Present Status of Artificial Pneumothorax Therapy.—J. A. Lyon states that while the apparent clinical results following the intelligent, persistent, and discriminate application of artificial pneumothorax therapy in certain cases of pulmonary tuberculosis, are an improvement in the general health, a gradual fall in the evening temperature, the return of appetite, an increase in the body weight, a gradual lessening of the cough, and a reduction in the amount of sputum, one should not recommend the use of artificial pneumothorax therapy as an infallible remedy applicable to all cases. Indeed, the results are often contradictory and disappointing and there is still much to learn. Not only is the somewhat general dictum that "artificial pneumothorax therapy can do no harm even though it should fail to benefit," fallacious in the light of the author's experience, but also definite and serious damage may result from its careless or ignorant administration as in the case of tuberculin.

6. X-Ray Diagnosis of Pulmonary Tuberculosis.—P. C. Bartlett notes that many cases of tuberculosis come to a physician when the diagnosis of this disease is not difficult to make. In making a diagnosis of tuberculosis in an early case, there is needed all the help possible from every source. The *x*-ray when used by an expert is a help in the diagnosis of early tuberculosis. The *x*-ray examination should be a part of the complete examination of the patient, but should not replace the ordinary well-known clinical methods of making a diagnosis. There are several types of cases in which the *x*-ray may be especially helpful. Chief among such conditions are phthisis associated with emphysema and bronchial gland tuberculosis in children.

9. Diagnosis and Treatment of Tuberculosis in Childhood.—W. C. Bailey employs the following procedure: He inquires very carefully as to the presence of an infecting case in the family, and if one is found, makes a provisional diagnosis of infection. Then he tries the von Pirquet test and if that is positive he makes a physical examination for signs of intrathoracic or intra-abdominal tuberculosis for the purpose of finding out whether the case is one of infection only or of disease. If the well-known signs of mediastinal gland infection are elicited and if there is no active disease in the lung or abdomen, the facts should be carefully explained to the family, the case should be reported to the proper authorities, and the child should be given special hygienic care at an outdoor school. If active disease is found, the child should be treated in a sanatorium or in a special outdoor school. In the event of a negative von Pirquet test, with a history of contact, the child should be kept on the suspicious list, placed in an outdoor school if possible, and the von Pirquet test should be repeated at appropriate intervals. If there is a negative history of contact and a negative examination but if there is a positive von Pirquet test, the procedure should be the same as in the case cited above, a careful physical examination being made always for the purpose of detecting the active cause. A change in board of health regulations should be made so that a physician may report cases of tuberculous infection as distinguished from cases of tuberculous disease requiring sanatorium care, whether these be open cases or not. In the cases in which contact is proved, but the von Pirquet test is negative, the physical examination should be made in the same way and the von Pirquet test should be repeated several times. In any event the name of the child should be given to the health and school authorities as that of a suspicious case requiring supervision.

11. Tuberculosis in Children.—R. M. Smith emphasizes the distinction between tuberculous infection and tuberculous disease. Tuberculous infection occurs in many instances without symptoms sufficient to attract any attention and then goes on unrecognized. It may give no signs on physicial examination, but usually thoracic and abdominal gland tuberculosis is made evident by the local signs of enlarged glands. There may be chronic enlargement of the bronchial or mesenteric glands from infection with some other organism than the tubercle bacillus. It is necessary to have a positive von Pirquet reaction to make the diagnosis of tuberculosis. The von Pirquet reaction may be taken as a safe index to tuberculous infection. The instances in which a negative reaction occurs in the presence of a tuberculous infection are usually instances which can be explained according to well-known facts. Unless the tuberculous infection is active, it is not a source of immediate danger, either to the individual or to the community. A child with such an infection should be treated, not as a patient with active tuberculosis, but as

an individual to be watched carefully, fed properly and put under good hygienic surroundings in order that the disease may not become active. Tuberculous disease means an active tuberculosis. This condition in children starts as a glandular disease, but has a great tendency to extend beyond the confines of its original seat within the gland, and when such an extension occurs there is apparently little further tendency to localization. It becomes at once a generalized process, leading often to rapid death. After the age of ten years, tuberculosis assumes the characteristics of adult tuberculosis, but before that age the diagnosis must be made on different evidence. The symptoms are usually very indefinite. There is little or no cough and almost never any sputum. The temperature is frequently not greatly elevated, and not more elevated than occurs in infants and young children from a variety of causes. Physical examination in the early stage of the disease reveals nothing other than a child in poor condition with enlarged glands. When the disease extends beyond the glands into other parts of the body the physical signs become more definite. In the lungs they may be those of bronchopneumonia and frequently this diagnosis is made when there is no suspicion of tuberculosis.

2. Pains Anomalously Distributed in Cardiovascular Disease.—H. L. Elsner emphasizes the frequency with which pain in any of the anterior thoracic regions, usually in the precordium, is associated with myocardial weakness and degeneration, at a period often preceding by many weeks the positive and other subjective symptoms of this serious condition. Embryonal heart sounds in the adult, with associated dyspnea and pain, should arouse the suspicion of degenerative changes in the heart muscle associated with vascular anomalies. In aortic insufficiency the force with which the heart strikes the chest wall often adds an element of discomfort referred to the intercostal and pectoral muscles. The character of the pains associated with vascular lesions varies materially. At times the pains are severe, burning, boring, tearing, or even pulling, or there is a persistent pressure as if a weight is resting on the sternum. Painful tremor referred to the heart is not infrequent. In some cases there are areas of hyperesthesia. Irregular and intermittent hearts with cardiac tumult are frequently associated with pain, either in the region of the heart or at a distance. This pain often increases as hypertrophy of the organ progresses. Sudden, severe, and alarming pain in the precordium, occasionally in the neck, accompanies each intermission in some cases and makes the patient conscious of a halting heart. There is a class of cases in which the blood pressure is normal, and in which there are pain in the precordium, anemia with numbness, vertigo, a sense of weight rather than pain in the region of the heart, no murmur, a small pulse, and a rapid heart during a long period; later dyspnea occurs, aggravated by movement of the arms. In these cases there is myocardial degeneration. The diagnosis is not made until the disease is far advanced unless one is alert. There is a class of cases of myocardial degeneration associated with slight degenerative changes of a sclerotic nature in the smaller arteries of the heart, in which there are transitory dilatations of the left ventricle, giving rise to evanescent systolic murmurs. These may be associated with severe precordial distress at times, particularly if the cases are of specific origin. As the tone of the hear improves, the pains yield and the dilatation and the murmurs disappear. When these cases occur in young subjects they are of either toxic or specific origin. If not relieved they lead to marked muscular insufficiency and frequent attacks of angina pectoris, and are often associated with aortic disease. In hysterical young women there is frequently a complaint of painful pulsation referred to the abdominal aorta in the epigastrium. Sometimes there are vague neuralgic pains radiating from this point. Pain referred to the thorax with dyspnea, with or without physical signs, aggravated by movement of the arms upward, may be considered to be of cardiac origin in most cases, particularly if such movement increases dyspnea at the same time. Most of the author's cases of so-called pseudoangina, not neuroses, proved ultimately, if in young subjects, to be due to cardiac syphilis with arterial and consecutive myocardial degeneration; in older subjects, they were a true angina dependent upon coronary changes. The following is an interesting and important group, demanding consideration: (1) Cases in which arterial changes are mainly limited to the abdominal vessels with sensory symptoms referred to the abdomen and associated with marked digestive disturbances. This condition Ortner has named dyspragia intermittens angiosclerotica intestinalis. (2) Cases which simulate those above mentioned, in which there is so-called subdiaphragmatic angina pectoris due to coronary disease, without marked changes within the abdomen, either in the organs or in their nutrient vessels. (3) Cases in which there are associated changes of a sclerotic nature in the coronaries and abdominal vessels causing both thoracic and abdominal symptoms.

6. Tuberculization and Immunization.—M. Fishberg notes that in civilized countries, especially in industrial cities in which careful investigations have been made, the population is thoroughly tuberculized. On the other hand, primitive peoples who have not come into intimate contact with civilized and tuberculized humanity have no tuberculosis at all. Individuals free from tuberculous infection are very susceptible to the pernicious effects of tubercle bacilli. Even the strong and robust constitution of the average rural inhabitant is of no avail when he comes into a tuberculous milieu, and he succumbs more easily than those who have been raised in cities, as is the case among certain immigrants in the United States and among primitive peoples hitherto exempt from tuberculosis who meet white settlers in their native lands. Their strong and extraordinary vulnerability in contact with tubercle bacilli is to be considered a physiological trait of humanity irrespective of race, geographical position, and social or economic conditions. This acquired immunity of the tuberculous to tuberculosis is the greatest safeguard against superinfections and reinfections with new strains of tubercle bacilli, which are ubiquitous and cannot be avoided in modern large cities. Experience teaches that primary infection is most dangerous during infancy and in the adult, while during childhood mild tuberculous infections are in the vast majority of cases benign and, because the body is thus immunized against reinfection, even beneficial. The prophylaxis of phthisis is therefore to be directed along the lines of prevention of massive infections of children, es-

pecially infants, because these are infections apt to be the forerunners of phthisis in the adult.

9. Pulmonary Tuberculosis Complicating Appendicitis.—A. C. Burnham states that a cough occurring after operation should always arouse a suspicion of tuberculosis. Mild cases of this disease usually stand operation very well, but should not be subjected to operation when the symptoms may be alleviated by other means. Moderately advanced cases, except very chronic arrested ones, usually stand operation very poorly. If operation is necessary, delay only weakens the resistance of the patient. Accurate diagnosis of the condition of the appendix is of far greater importance in patients with pulmonary tuberculosis than it is in patients otherwise healthy. The purulent or gangrenous appendix should be removed as early as possible, while the catarrhal or mildly inflamed condition is better dealt with more conservatively.

2. Use of Small Deep Skin Grafts.—J. S. Davis calls attention to the value of very small grafts, especially those which contain more of the true skin than the superficial grafts advocated by Reverdin. The author has called these grafts "small deep grafts." It has been the author's experience in a large number of cases that the grafts which are somewhat deeper and contain more of the true skin give a more stable healing, and the final result is more like the normal skin in character than when the thinner grafts are used. The grafts may be placed on fresh wounds, but are usually applied to granulating surfaces. The success of small grafts depends to a large extent on the condition of the granulating wound, and it is most important that the granulations be clean, firm, rose pink in color, and not exuberant. Time is saved in the end by careful attention to this point. It is of advantage to place these grafts on a granulating surface, as there is no pain in the preparation of the surface, no danger of stirring up infection, and no loss of blood, which is an important point in cases already much depleted. On the day preceding the operation, all secretions and crusts are removed. The granulations are painted with tincture of iodine and dressed either with balsam or Peru and castor oil, 1:3, or with moist boric or salt gauze. The dressings are removed at the time of operation, and the wound is washed carefully, without causing bleeding, with sponges dipped in warm salt solution. The surface is dried thoroughly and a pad of dry gauze is placed over the wound; it is pressed down firmly on the granulations, and removed only when the operator is ready to apply the grafts. The surface to be grafted should be perfectly dry, as the grafts adhere much better to a dry surface and are less liable to be subsequently displaced. The simplest way to obtain these grafts is to pick up a bit of the epidermis with a straight intestinal needle held in an artery clamp. It is raised so that a little cone is formed and the base of the cone is cut through by depressing the blade of the knife. The graft, still on the needle, is transferred to the wound, with raw surface downward. The grafts are placed in rows, a space of not more than 5 mm. being left between the grafts. When two rows are in place, a strip of dry sterile rubber protective about 1.5 cm. wide is applied over them, so that the lower edge of the protective just covers the lower row of grafts. Then the protective is pressed down over the grafts firmly with a gauze pledget, and the edges of the grafts will uncurl and spread out evenly on the wound. The next row of grafts is placed close to the edge of the protective, and after two or three rows are applied they are covered with a second strip of protective, which overlaps the first piece about one-half its width. The protective is pressed down firmly, and the procedure is continued in this manner until the whole wound, or the part selected, is covered. The ends of the protective strips which extend beyond the wound edges may be fastened securely to the normal skin by means of a few drops of chloroform. Moist salt gauze over the protective strips secured by a bandage is a satisfactory dressing. The part should also be immobilized as far as possible. The area from which the grafts are taken may be dressed with boric acid ointment spread on a sheet of rubber protective, which is snugly strapped over the wound, or with silver-foil and dry gauze. The grafts are either round or irregularly oval. They vary between two and four mm. in diameter and should seldom be larger than 4 mm. They are thickest in the center and taper off toward the edges. With a sharp knife the size, contour, and depth can be judged quite accurately. The dressings should be removed on the second or third day, and any wound secretions should be carefully mopped up or washed off with a gentle irrigation by means of physiological salt solution.

3. Intrinsic Cancer of the Larynx.—Sir St. Clair Thomson concludes that cancer of the vocal cords in its early stages is a very slowly progressive and strictly limited process. Alteration of voice is the principal and may be the only symptom. Persistent hoarseness in any patient calls for a definite diagnosis. This is based chiefly on inspection of the larynx. Only in certain cases in which the growth is a superficial one and not an infiltrating one can it be confirmed by microscopic examination. The growth, even when it occupies almost the entire length of a vocal cord, can sometimes be completely removed by endolaryngeal operation in early cases. But this completeness can be ascertained only when, by laryngofissure, the remains of the vocal cord and adjoining soft parts have been removed and submitted to the pathologist. Laryngofissure is, therefore, the operation of choice in all cases of endolaryngeal cancer. The operation offers the very best prospects, because the disease remains for some time superficial and limited and because laryngofissure cannot be considered a dangerous operation. Statistical results show a lasting cure in 80 per cent. of cases, and if all patients presented themselves and cases were diagnosed early there is no reason why the results should not be even more satisfactory.

1. Dysentery.—F. M. Sandwith devotes his second lecture on this subject to amebic dysentery. The large intestine of man is liable to infection by two distinct entamebæ. One of these *Entameba coli* is a harmless organism, living merely on the intestinal contents and never penetrating the mucous membrane. The second entameba, the *Entameba dysenteriæ* (*E. histolytica*, Schaudinn, or *E. tetragena*, Viereck), is a pathogenic organism which not only lives among the intestinal contents, but actually invades the tissues of the large intestine, leading to all the troubles and symptoms associated with amebic dysentery. The primary lesion of amebic dysentery is apparently an exudation into the submucous coat of the large intestine, first seen to the naked eye as red, slightly raised spots, not much larger than the head of a pin. When these congested spots grow in area a yellow central point appears, which is the earliest stage of ulceration, due to local necrosis of the mucous membrane. Amebiasis is a convenient name for specific lesions in various parts of the body—intestine, liver, brain, skin near anus, etc.—and amebic colitis has been proposed as a preferable term to amebic dysentery, because it includes the sporadic mild cases, even when accompanied by constipation, in addition to those characterized by frequent evacuations and the constant presence of tenesmus, blood, and mucus. The existence of tenesmus, often the symptom forcing the patient to seek medical aid, means that there are lesions in the proximity of the sphincter. If the lesions on the contrary, either in true dysentery or in bilharzial infection, are limited to the colon, there will be no tenesmus. The onset of amebic dysentery is usually sudden and always begins with diarrhea. Fever is not a marked feature, and when present is never high. The pain is intestinal, and is specially great before and during an evacuation. A higher degree of leucocytosis, tenderness over the colon, and thickening of the large intestine are all in favor of the amebic type. The cause of death in amebic colitis is generally perforation and consequent peritonitis, succeeding ulceration of the colon or appendix. Sandwith agrees with other writers on tropical diseases that the most frequent complication of amebic dysentery is abscess of the liver.

4. Persistent Low Arterial Blood Pressure in Carcinoma of the Tongue with Amyloid Disease.—H. D. Rolleston reports the case of a man aged 62 years suffering from an inoperable cancer of the tongue in whom a persistent low arterial blood pressure was presumably due to the general asthenia and the amyloid disease. This was unique in the author's experience, as he has not seen a blood pressure as low as 70 mm. Hg., except in cases of advanced Addison's disease and in cardiac failure shortly before death. In otherwise healthy persons during the fever of pneumonia the author has seen a systolic blood pressure of 80 mm. Hg. In the above case, the diastolic blood pressure taken by the auscultatory method ten days before the final collapse, was 35 mm. Hg., with the normal difference of 30 mm. between the systolic and diastolic pressures.

5. Conditions Simulating Chronic Appendicitis.—J. Morley states that Jackson's pericolic membrane may give rise to symptoms simulating chronic appendicitis. In the condition of mobile proximal colon, which is a reversion to the primitive pronograde arrangement, the patient is predisposed from birth to constipation and the various ills resulting from it. Symptoms resembling chronic appendicitis may result, or there may occur actual inflammation of the appendix, but in either case the right surgical procedure is not a simple appendicectomy but a fixation of the colon back into the right loin. The commonest cause of an erroneous diagnosis of chronic appendicitis is right tuboovarian disease, often of gonorrheal or septic origin. In such cases a spasmodic contraction of the right psoas muscle sometimes occurs on palpation, which contraction may be mistaken for an abscess or a neoplasm.

7. Rupture of the Kidney from Slight Trauma.—J. L. Atkinson states that rupture of the kidney is a comparatively rare result of trauma, more particularly so when the actual kidney tissue itself is lacerated. Keen quotes Kuster's statistics of injuries under his observation in the clinics of Berlin and Basle, and these show only 10 cases in 7,741 injuries, or a little over 1 in 1,000. Israels, with a large experience of renal surgery, had only one operative case. But in practically all cases met with either in actual practice or in the records, the condition has always been caused by a severe accident, such as falling from a height, crushing between buffers of a train, or by the wheel of a heavy cart passing over the abdomen. In the author's patient, a girl fourteen years of age, rupture of the kidney was caused by a fall from a veranda whose floor was eleven inches from the ground. The girl had run a distance of fifteen feet and had plunged through a wire netting at the end of the veranda. Profound shock and hematuria pointed to the real nature of the lesion. This was confirmed by operation on the following day. Recovery ensued.

Severe, Fatal Infection of Mankind with Bovine Tuberculosis.—Beitzke relates the following case: A boy, aged fourteen, began to lose his appetite, then to vomit. He lost flesh as a result and a cough set in. Pain beneath the diaphragm had been present from the start. The case proved a puzzle to a number of practitioners. Admitted to a hospital with diagnosis of severe anemia, both liver and spleen were found enlarged. To the

right and behind was heard a pleuritic friction sound. Red blood cells 5,660,000, white blood cells 8,439. Temperature 38° C. Patient lived six weeks after admission, dying of progressive exhaustion. Edema and ascites developed before death. A brief summary of the case after study of autopsy finds is as follows: boy of 14, ill in all six months, dead of progressive marasmus. Generalized tuberculosis of an unusual and severe type. The amount of caseation in the enlarged lymph glands and spleen exceeded anything ever seen by the author. Both lungs contained uniformly distributed large and round caseous foci—an unusual find. The process had evidently begun in the mesenteric glands, with secondary involvement of the mediastinal and supraclavicular glands, speaking unqualifiedly for an abdominal infection. Bacteriological studies showed undoubted bovine tuberculosis, inoculation experiments giving positive results. The boy had played daily in the cow stable, and had drunk raw cow's milk. The ancestry was sound and the boy himself was healthy. His exposure to the cows had been prolonged, lasting over months. It does not appear that the milk he drank could be traced to any particular infected cows, for nothing of this character is adduced. In 1912 Weber published a collection of 138 cases of bovine tuberculosis in man, and the author increased this number to 264 cases without exhausting the literature.

Case of Diphtheritic Polyneuritis.—Friedlander relates a case which occurred in his own person. He was fifty-seven years old when he contracted diphtheria from a child patient. The case was a very severe one both for its local and systemic manifestations. The fauces, palate, and pharynx were covered with membrane. On several occasions circulatory failure was threatened. Insomnia was troublesome and there were drawing pains in the lower limbs, relieved by aspirin. Four weeks after the onset of the disease, while he was recuperating at a resort, he was seized with a violent backache and pain over the sacrum. A week or so later his feet felt benumbed while walking. A slight paresis of the left hand led to the diagnosis of polyneuritis. There was developed an ataxic gait and loss of knee reflex with intolerable pain in the limbs. As the author's mental state showed participation in the disease he was taken to a sanatorium. By reason of several pareses he was unable either to feed himself or swallow readily. There was loss of cenesthesia, so that he could not perceive the locality of the various members. Paresis of the sphincter ani had led to prolapse of the rectum. Anorexia had developed, with repugnance toward certain foods. The calf muscles and interossei showed marked atrophy while a number of others were more or less involved. The circulation was very poor, the hands being like ice. The nerves of the four extremities were involved with exception of the sciatics. The involuntary reflex acts were abolished (sneezing, etc.) and perspiration ceased. Despite all the grave symptoms the cardiac action was good, the kidneys had not been compromised by the disease, and no bedsores developed. There was gradual recovery, promoted by sojourns in Gardone and Aachen, and by physical therapy.

Deutsche medizinische Wochenschrift.

August 6, 1914.

Extinction of the "Diseases of Unculture."—Kisskalt refers to certain diseases which appear to die out as a result of civilization and its implied sanitation, especially typhus, recurrent fever and bubonic plague. Vaccination also controls smallpox. Recently, however, we have learned much concerning epidemiology. Typhus as a louse-borne pestilence is readily controlled by steam disinfection of clothing and the simple application of soap and camphorated oil to the surface of the individual. In this way the disease is kept in check in Tunis. Mere sanitation alone accomplishes little or nothing against this affection, and its recession is due to increased knowledge founded on animal experimentation. Recurrent fever, also louse borne is similarly checked by an antilouse campaign. Variola, on the other hand, is not spread by vermin, and its present status is that of measles and scarlatina. Sanitation has not prevailed against these affections, although quite recently there appears to be a falling off in scarlatina mortality. Recession of the bubonic plague in recent centuries is now readily intelligible as it is a rodent-borne disease in which the flea is the direct carrier. It is doubtless connected with the suppression of the old black house rat, which was completed during the 18th century. The causes of this suppression are not known. The socalled migratory rat, a much less familiar animal, is believed to have had much to do with it, and the multiplication of domestic cats may also have played a part. This does not explain fully how rat plague came to die out, as rats are still with us in abundance. At present we can only adduce the possibility of an acquired immunity. As is known to bacteriologists there is a socalled pseudo-tuberculous bacillus in rodents which resembles very strongly the *Bacillus pestis*, of which it may be an avirulent successor.

Internal Calcium Therapy.—Boruttau refers to the increasing importance of mineral matter in our studies of normal and pathological metabolism, especially in regard to calcium addition in deficiency diseases. Emmerich and Loew have recommended the addition of inorganic calcium to bread, while several trademarked preparations are being marketed as additions to infant's milk. The calcium compounds most used are the chloride and lactate. To make any impression on deficiency diseases (nervous affections, spasmophilia) large dosage and persistent use are neeessary. The author suggests a combination of calcium and plant seed albumin (edestin) as a purin free nutrient. Artificial asthma in animals as a result of intravenous injection of hypophysis extract, can be prevented by preliminary treatment with injections of calcium chloride. Such results can hardly be explained by the mere making good of tissue defects. It is probable that the calcium ions circulating in the blood exert a specific action on the muscles and nerves as a result of altered concentration.

Mechanical Treatment of Impotence.—Flatau assumes that fifty per cent. of functional impotence is amenable to treatment—almost twice the percentage computed by Fürbringer. The very large fraction of incurables, however, may possibly benefit by some purely mechanical contrivance to the extent of securing sufficient temporary rigidity to impregnate women. It is the elderly man and worn out rake who are often among those who wish to marry for the sake of an heir, and from the eugenic viewpoint children begotten by such males are undesirable as doomed to inferiority. The author therefore would interest himself only in the otherwise robust who are psychically impotent, and who are extremely anxious for an heir. Numerous devices are on the market, but their use is connected with serious drawbacks. They are expensive and difficult of application. In these cases of impotence precocious ejaculation is very often present, thus defeating the purpose of the erection; and the mere manipulations connected with fitting the apparatus to the genitals will frequently have this very result. The author knows of no apparatus yet devised which is practicable.

Insurance Medicine.

Surgery of Gastrointestinal Disease in Its Relation to Life Insurance.—Dr. William J. Mayo, Rochester, Minn., states that in anticipation of the questions which confront life insurance companies, a review of what surgery has accomplished in its relation to the prolongation of human life is important. The insurance company must know as accurately as possible to what extent an average risk has been increased by a surgical operation and whether a patient will be benefited sufficiently by an operation to warrant the insurance company in urging that it be performed. If death may be averted or life prolonged, it then becomes a matter of economy for the company to have the operation performed as early as possible. It is assumed that in estimating the curability of the disease for which the operation is performed, the surgeon is a thoroughly competent one, familiar and experienced in the methods of procedure. An estimation as to the curability of any gastrointestinal disease based on data that was accumulated previous to five years ago is practically worthless. We formerly believed that simple ulcers occurred in the stomach in 95 per cent. of the cases, now we know that 75 per cent. of them are in the duodenum. The condition was supposed to be much more common in women than in men; we now know that at least 75 per cent. of the cases occur in men. We believed that the lesion was usually multiple; we now know that it is single in 95 per cent. of the cases. We believed that the taking food gave rise to pain; we find on the contrary that food gives relief to pain. Hemorrhage is a diagnostic symptom in not more than 20 per cent. Sudden hemorrhage from the stomach with no other symptom of an ulcer is not indicative of ulcer. Ulcer of the stomach is not quite so favorable for operation as is ulcer of the duodenum because of the frequency with which cancer is engrafted upon it, rendering it imperative to excise if possible. A slight increase in operative risk is therefore accepted in order to secure better ultimate operative results. It is quite within the limits of truth to say that 98 per cent. of patients with duodenal ulcer and 95 per cent. of patients with gastric ulcer may be cured by a well-chosen, properly executed operation. The operative mortality for duodenal ulcer, including all causes, is about 1½ per cent. That of gastric ulcers which include the large callous ulcers in which resection is necessary, is from 3 to 4 per cent. Complications arising as the result of the operation are extremely rare. Under the improved methods of diagnosing cancer of the stomach, especially by the Roentgen ray, which makes early recognition possible, we may expect a yet higher percentage of cures following operation. The reexamination for life insurance purposes by competent medical examiners will have a great influence in the detection of such growths while they are yet in the curable stage. Resection of the stomach for cancer gives about 25 per cent. of 5-year cures and the operative mortality is about 10 per cent. Gallstones may be considered foreign bodies and, other things being equal, the earlier these foreign bodies are removed the better for the patient. In patients who are good risks for operation the removal of gallstones has only a small mortality, not over ½ per cent., and the patient becomes a good insurance risk at the end of a year. When the gall-bladder becomes so diseased that it can no longer functionate, it must be removed. Mayo states that about 80 per cent. of his cases from this trouble come to him in this condition, and in many of these cases cancer was found in an early stage. He urges early operation in cases of gallstone condition in order to avoid cancer of the gall-bladder and liver, and also involvement of the common duct and secondary involvement of the ducts of the liver and pancreas. The immediate mortality of operations on the common duct is much greater than for stones in the gall-bladder. Taking cases as they come, usually with jaundice, infective cholangitis and changes in the blood incident to the disease, the mortality is probably from 5 to 8 per cent. Considering their importance, extent and nature, the small intestines are rarely diseased, probably by reason of resistance brought about by their long heredity. Immediately beyond the stomach, which has the highest percentage of cancers, is the small intestine which relatively has the least. The number is so small as to have little bearing on the question of its relation to life insurance. The appendix and its diseases may be considered a closed book, as the probabilities are that the individual who has lost his appendix is in no greater danger from complications than is the individual who has not had his appendix removed of having trouble with it of any equally severe grade. Surgery of the large intestines introduces some new and complex questions. Many believe that in the colon lies the cause of serious ills which bring on degenerative changes in vital organs and also the symptom-complex which we term neurasthenia. It has been shown that we now consume four times as much flesh per capita as we did 100 years ago. Decomposition of vegetable matter results in fermentations which produce mostly harmless combinations; decomposition of meats results in putrefaction with the development of poisonous bodies. In this manner so-called intestinal intoxication may have its origin. Short-circuiting the ileum into the sigmoid and removal of the large intestine are being practised for relief of degenerative and neurasthenic conditions. The subject is so new that it would not be profitable to discuss its effect on insurance. Tuberculosis of the large intestine of the hyperplastic variety is more common in the vicinity of the secum and ascending colon. It gives the clinical symptoms, and, when removed, many of the physical appearances of cancer, and is often due to the bovine type of tubercle bacilli. It is usually localized, that is, the individual has no other evidences of tuberculosis. As a rule all of the cases suitable for operation have remained well after excision. Intestinal diverticula, which occur in the large intestine, may cause a condition strongly resembling cancer. It is important, therefore, when a tumor of the large intestine is removed that it be examined microscopically to determine its exact nature. Operation for cancer of the large intestine gives favorable results; fully 50 per cent. of such patients have lived for five years and were apparently well at the end of that time. The only prophylaxis for cancer is the removal of sources of chronic irritation. The insurance company may, by means of the re-examination of the insured, prevent many deaths from cancer and greatly increase the length of life of the insured. Many of these conditions are even more important in relation to chronic infections and anemias from which may start cardiovascular disease.—Medical Section American Life Convention.

Book Reviews.

DIE IMMUNITÄTSWISSENSCHAFT. Eine kurzgefasste Übersicht über die biologische Therapie und Diagnostik für Ärtze und Studierende. Von Dr. HANS MUCH, Oberarzt am Eppendorfer Krankenhause. Zweite völlig umgearbeitete Auflage. Price, 8 marks. Würzburg: Carl Kabitzsch, 1914.

THERE is perhaps no more satisfactory single volume on our knowledge of immunity than this monograph by Much. The author is a well-known investigator in this subject, who has contributed much of fundamental importance to his specialty. His style is lively and clear; and he writes from the point of view of the practising physician, consequently presenting his subject in a form more useful than is usually seen in the work of purely laboratory workers. From another point of view the book is very personal, the author freely expressing his own ideas, though they do not agree in some cases with those current. He does what is very rare in Germany, omits all references to literature, but the work gains by these very limitations; it is more compact and less involved.

After an introductory chapter on general principles he turns to a discussion of the meaning of the words, immunity and virulence; then classifies the three types of immunity, and finally begins his practical subject: the immunization against poisons, using diphtheria as an example. He points out the difficulty of handling the well-known cases of diphtheria carriers, whose throats are often filled with virulent organisms although the general health of the persons suffers not at all. Such people are often more dangerous than those actively ill of diphtheria, for they go unguarded among healthy people to whom they can communicate the disease. He insists properly on the importance of the early administration of diphtheria antitoxin and discusses the statistics with great clearness, showing that if the remedy is given on the first or second day of the disease the mortality is almost negligible; whereas late injections have but little value, as large quantities of toxin have been formed and the tissues injured beyond repair before the antitoxin reaches the circulation. The question of protective inoculation is also handled with a great deal of skill. He shows that such inoculations do not protect for any very long period, giving as an average ten days. He recommends Schick's intradermal test for the presence of sufficient toxin in the blood to give protection and also warns against the general use of the Behring active immunization method by the injection of a mixture of active toxin partially or completely neutralized by antitoxin. He also commends very strongly the intraspinous or intradural injection of tetanus antitoxin, a practice which has recently been revived both in this country and abroad, owing to the poor effects which are obtained by a subcutaneous or intravenous exposition of the drug. In some forms of bacterial infection he feels that the body can be assisted in its contest against the invasion of the organism by the induction of a general leucocytosis, by the injection of hetol, or by the production of a local leucocytosis by the use of sodium nucleinate. He also thinks that the injection of a serous fluid into abscesses rich in leucocytes is of help, a process which has been used by the surgeons in cleansing indolent ulcers and granulating wounds. He advises the transfusion of fresh plasma obtained by adding 1.5 per cent. of sodium citrate to the blood of a healthy person so as to prevent coagulation, and then reinjecting about 100 c.c. of this mixture. These examples are quoted only to show that the author does not follow the example of many of his countrymen and leave the therapeutic side entirely untouched. In acute septic disease he feels that vaccine therapy is entirely worthless. While he admits its value in chronic conditions, he considers that the use of an autogenous vaccine is not always to be preferred, for he points out that the body is already immunized to a certain extent against its own organism which is causing the infection, and that, therefore, a closely related strain of the same species should be used. This, of course, is opposed to Wright's belief that the benefit of the vaccine comes from stimulating the tissues which have not yet reacted to the organism which is inciting the infection.

In the treatment of syphilis he takes the point of view that the Wassermann reaction is merely an expression, and an unspecific expression, of a damage to the tissues of the person showing the reaction and that, therefore, treatment should be continued until the Wassermann reaction is negative. He takes issue with those who think that the Wassermann reaction is a specific immunity reaction and says that if this is the case it would be a mistake to destroy by treatment an immune antibody circulating in the blood. The negative reaction, however, does not show immunity, but only that the diseased tissue has ceased to figure, though the parasites may still exist; but of this the Wassermann affords no proof.

In regard to the recent work of Abderhalden on the subject of protective ferments he is distinctly sceptical. His own tests have been entirely negative, and he doubts the scientific information which Abderhalden has given as the basis of the reaction. He does not, however, deny the possibility that experience may show the test to be of clinical value, in spite of the lack of scientific foundation.

These abstracts are sufficient to show that the writer has produced a very interesting, readable, and useful review of the present position of immunity, as it aids the physician in diagnosis or in treatment.

PRACTICAL HORMONE THERAPY. A Manual of Organotherapy for General Practitioners. By HENRY R. HARROWER, M.D., Sometime Professor of Clinical Diagnosis, Loyola University, Chicago; Fellow of the Royal Society of Medicine; Fellow of the American Medical Association. With Foreword by Professor Dr. Artur Biedl, Vienna. Price, $4.50. London: Baillière, Tindall & Cox; New York: H. R. Harrower, 880 West 180th Street, 1914.

IN this, the latest contribution to the subject of the internal secretions and of their value as medicinal agents, the author displays a comprehensive knowledge of the extensive literature of this subject. Indeed, with the references in the text and the bibliographical lists at the end of each chapter, there is presented a digest of almost everything that has been written on this subject. In giving this book the title "Practical Hormone Therapy" the author has applied the epoch-making conception of Starling to the entire series of internal secretions. These are contrasted with the enzymes as regards their greater resistance to heat and as regards the fact that "a ferment consists of the product of the cell producing it, the proferment, *plus the hormone*." This book is divided into eight sections which deal respectively with the general aspects of hormone therapy, the hormones of the digestive system, the metabolic glands, the nervous system, the reproductive system, the vascular system, and miscellaneous topics, such as the use of pluriglandular extracts. An appendix contains a glossary of terms, an organotherapeutic dosetable, and a list of books on the internal secretions. In turning the pages of this book one cannot but admire the zeal with which the author has collected the data pertaining to the therapeutic efficacy of the internal secretions. At the same time one feels that the scientific value of this book is impaired by an excess of enthusiasm in extolling the value of organotherapy.

DAS HYGIENISCHE A B C FÜR HERZKRANKE. Von Prof. Dr. HEINRICH STERN in New York. Mit 6 Abbildungen im Text. Price, 2.50 Marks. Würzburg: Verlag von Curt Kabitzsch. Pages 148.

THIS book is addressed to those of the laity who suffer from heart disease or to those who are in danger of becoming heart sufferers. In a simple, clear way the patient is told of the heart and its functions, the diseases of the heart and the mode of life is pointed out. The patient is shown the purpose of the doctor's orders and can thus better cooperate with him. Courage and the joy of living are instilled into him. Therapy is omitted except those few little things that the patient can do for himself.

LUXOR AS A HEALTH RESORT. By W. E. NICKOLLS DUNN, M.B., Lond., M.R.S.C., L.R.C.P., and GEO. VIGERS WORTHINGTON, M.B., B.C., Cantab., M.R.C.S., L.R.C.P., Superintendent Medical Officers to the Luxor Hospital for Natives Price, 1/6 net. London; H. K. Lewis, 1914.

COMPARATIVELY little is known by the profession in general, and less by the public, of the conditions in Egypt, of its advantages and drawbacks, of its virtues and dangers. It is with the idea of giving a short and clear account, which may be a useful guide to the profession and public alike, that the writers have ventured to set down these few practical notes, gleaned from several years' experience in Upper Egypt.

Society Reports.

AMERICAN PEDIATRIC SOCIETY.

Twenty-sixth Annual Meeting, Held in Stockbridge, Mass., May 26, 27, and 28, 1914.

THE PRESIDENT, DR. SAMUEL MCC. HAMILL OF PHILADELPHIA, IN THE CHAIR.

(*Concluded from page* 571.)

Thursday, May 28, 1914—Third Day.

A Case of Primary Splenomegaly of the Gaucher Type.—Dr. J. H. MASON KNOX and Dr. R. H. WAHL of Baltimore reported this case, which occurred in an infant 11 months old. The child had never thrived and weighed only 11 pounds. General malnutrition was associated with idiopathic enlargement of the spleen, liver, and lymph glands, and a peculiar yellowish pigmentation of the skin of the exposed parts. The blood picture was normal until a few days before death, when it assumed the appearance characteristic of lymphatic leukemia. At autopsy the liver, spleen, and the lymphoid tissues were very much enlarged and firm. Histologically there was more or less complete disappearance of the lymphoid elements, which were largely replaced by large swollen rounded or polygonal cells with small nuclei and abundant foamy appearing cytoplasm. The affected organs showed a variable amount of iron-containing pigment. In this case the large cells apparently arose from both the endothelium and the recticulum. The picture in the spleen resembled that first described by Gaucher in 1882. The condition suggested a systemic disease of the lymphaticohemapoetic tissues, but apparently any reticulated tissue might be involved. The condition was very probably related to other blood diseases.

A Case of Gaucher's Disease.—Dr. CHARLES HERRMAN of New York reported this case, which presented the following manifestations: A marked enlargement of the spleen, and a moderate enlargement of the liver; no distinct enlargement of the lymph nodes; discoloration of the face, especially around the nose, and a wedge-shaped thickening of the conjunctiva on either side of the cornea; persistent leucopenia and a tendency to hemorrhages, especially from the nose. The size of the liver and spleen did not change materially during the seven years that the patient was under observation. As the disease progressed the blood showed a marked decrease in the percentage of hemoglobin (75-45), a slight decrease in the number of red blood cells (4,390,000-3,400,000), a constant leucopenia with a decrease in the percentage of polynuclear leucocytes (70-48). As a result of splenectomy, in addition to a marked improvement in the general condition, there was an increase in hemoglobin (40-55) and red blood cells (3,400,000-4,000,000) and a much more marked increase in the white blood cells (4,400-15,000) with an increase in the polynuclear leucocytes (48-75). Splenectomy seemed justifiable even though the benefit might be only temporary, since all other forms of treatment had failed. The risk of the operation was no greater than that of similar operations for other conditions.

Dr. THOMAS S. SOUTHWORTH of New York asked Dr. Herrman if he had recommended operation for the sister of the patient whom he said was also suffering from the disease.

Dr. L. EMMETT HOLT of New York asked what results had been secured in the cases operated upon.

Dr. J. H. MASON KNOX of Baltimore said he wished to emphasize what Dr. Herrman had said in regard to the difficulty of making a diagnosis in these cases unless there was another case in the same family. The advisability of doing a splenectomy early in the course of the disease was a difficult problem as one did not know to what extent the disease had spread to other organs. It might be possible by means of a trochar to get a specimen of the spleen pulp for a pathological examination from which one might make the diagnosis. This would not be a dangerous procedure.

Dr. CHARLES HERRMAN of New York, in reply to Dr. Southworth's question, said that it would be difficult to get the consent of the parents to such an operation unless the child was in immediate danger. Dr. Mason's suggestion in reference to getting a specimen from the spleen for examination he had no doubt would some day be made possible. As to the cases reported, the first was Dr. Boviard's case, operated on by Dr. McCosh, and did not attract much attention. Of the nine cases reported that had been operated on, six recovered and three died. The oldest was 37 years of age and the youngest three years. In the future more cases would be operated upon and the operation would be done earlier. The cases reported had been followed only a few years and it was too soon to judge of ultimate results. Operation was justifiable as drug treatment was of no benefit.

Shall a Department of Pediatrics Include in Its Curriculum the Theoretical and Practical Training of Medical Students in Social-Medical Work Among Infants and Children?—Dr. HENRY J. GERSTENBERGER of Cleveland, Ohio, presented this paper. He said that in a similar paper last year Dr. Gittings had declared that "Between the prevention of disease and the preservation of health there is no essential difference and surely the physician, and not the sociologist, should become the logical arbiter of all problems relating to health." Dr. Gerstenberger said that if we were willing to take the first step we must be ready to take the second and see that the "logical arbiter" was trained for his work. In order to be effective all preventive work must be built upon the sound basis of scientific medicine. In consequence only medical men could direct such work, and therefore it was the duty of the medical schools to see to it that this medical training was given to students. The ideal plan for such work and instruction would be one dispensary in a small district with a well-trained full-time physician in charge aided by an adequate nursing staff, a social worker, and such assistant physicians as might be required to care for all the medical and social ills of the people in that district, except obstetrical and post-partum cases. This physician should have as his administrative head the Commissioner of Health and as his vigilant advisers and counsellors for the different parts of his work men at home in their special fields of medicine, these same men to be the heads of their respective departments or subdepartments in the university medical school; for the reason that after all was said and done our greatest hope for completeness of knowledge for ideals, and for stable policies in medical education in America, were the universities. This plan would give the student the opportunity to get in touch with practical work. Such a plan was being followed in Cleveland. During the senior year the class was divided into four sections and each section spent one-half to two hours for eight consecutive weeks in the wards getting an experience in contagious disease, in the milk laboratory of the Babies' Dispensary, and by practical work among babies in the homes of the poor. This work was appreciated by the men and he felt convinced that the seed had been sown and that men would take advantage of the opportunities offered to prepare themselves for this new field.

Dr. HENRY DWIGHT CHAPIN of New York called attention to the differences between institutional and private work and stated that many an interne that made a good record in the hospital failed to adjust himself to the conditions met in the homes of the poor. If the university could give this instruction it would be a great advantage. The most crying evil of the day was that men were turned out with insufficient training. At the Children's Hospital in New York the first step in social service was taken in 1900 and now every home was visited by a social worker and the physician was acquainted with the home surroundings of every patient. For the social work they had at first tried women physicians, but found that the nurse did better. He did not know why, but the work required a peculiar personality involving tenderness and sympathy; the workers must be something more than trained technicians.

Dr. A. D. BLACKADER of Montreal, Canada, thought it was a question whether this ideal in teaching could be realized owing to the lack of time. At McGill University the fifth year was devoted to clinical work and during this past year one morning a week was given to pediatric work. It was their aim to equip men as well as possible for general work and he did not see where they would get the time for doing the social work. He said he was glad Dr. Gerstenberger had spoken of the useless overfeeding in tuberculosis that was being done by the enthusiastic social and philanthropic agencies and of the needless giving of certified milk.

Dr. L. EMMETT HOLT of New York told of the time given to the teaching of pediatrics at the College of Physicians and Surgeons and did not think that conditions were as bad as had been pictured. Pediatrics

got as much time as obstetrics and some other subjects and it was being more and more recognized all over the country. The men at Columbia were given a very good idea of what pediatrics meant and the work had to be done for a degree. Dr. Holt urged the members to take a more active part in the sociological side of pediatrics and to join the Association for the Prevention of Infant Mortality.

Dr. Fritz B. Talbot described the social work in connection with the Massachusetts General Hospital and said they now thought they could not get along without this aid to their hospital work.

Dr. J. H. Mason Knox of Baltimore said he wished to endorse what Dr. Gerstenberger had said. If people had waited for this Society to do preventive work many babies would have been lost. The members of this Society should take a part in work of this character and should interest others in it even if they did not have the time to do the actual work themselves. Infant consultations furnished an opportunity for the medical student. Here the student would see the babies week after week when they came for advice as to how to keep well and would thus become interested in the work of prevention and would go out with a knowledge of how to keep babies well as well as of how to cure them after they had become sick.

Dr. John Lovett Morse of Boston told of the pediatric work that was being done at the Harvard Medical School, and said that they now proposed to put the fourth year men in the baby hygiene stations. Dr. Morse was of the opinion that there was not sufficient correlation between the various agencies engaged in the work of looking after the children and in the prevention of infant mortality.

Dr. J. C. Gittings of Philadelphia said that from present indications we would soon be on the Chinese basis. He said he wished to emphasize how strongly he felt on this subject. The physician with a well established practice did not have time to do a great deal of the preventive work, but he could extend his sympathy. It was necessary to have trained directors and now that the attention of students had been drawn to this work he believed that men would qualify.

The Pathology and Prophylaxis of Rickets.—Dr. Joseph E. Winters presented this communication, in which he described the abnormalities in ossification which showed conclusively that whatever inhibited assimilation of salts in food caused rickets, and that which insured assimilation of salts in food prevented rickets. Salts to be assimilated must be in organic synthesis with protein. In every food produced in the laboratory of nature salts were in organic synthesis with protein. Disintegrate this synthesis and every food was a rachitic food. Condensed, evaporated, dessicated milk, whey powder, and every dry preparation of milk was a rachitic food. The synthesis of salts with protein in milk was light, hence easily disintegrated. The child fed on cereal might be extremely emaciated and markedly rachitic. Cereal dextrose, glucose, maltose and malt soup inhibited the assimilation of salts in young infants and engendered rickets. Hit or miss modifications of skimmed milk were also productive of rickets. Digestion of protein was by gradual erosion, therefore the young infant could not digest protein unless in finely divided particles, that there might be innumerable points of catalytic action of enzymes. The neglect of the physical behavior of protein superinduced rickets in that it precluded salt assimilation. Centrifugal cream was a rachitic food since it was a protein free food. Ample protein was requisite for salt assimilation. In order to make easy the digestion of protein use the top one-half ounce from a quart bottle of milk sixteen hours after milking, diluted with water and lime water and administered at the proper temperature; this yielded an immense number of finely divided light feathery flocks, easily reduced to a semi-emulsified condition by stirring. The prophylaxis of rickets must be sought in the physical behavior of protein. The proportion of salts in mother's milk was diminished with the increasing age of the mother, in the later months of lactation, during pregnancy, in lactation, and from frequent pregnancies, and might be the cause of rickets. Syphilis, tuberculosis, or malhygiene, predisposed to, but did not cause, rickets.

Dr. Rowland G. Freeman of New York said it seemed to him that it was time to stop considering rickets as a disease due to food at all. Food never caused it though it might modify the course of the disease. Some of the worst cases of rickets in his experience had been in breast fed children, where the breast milk was good. Rickets usually occurred in people from the tropics and developed during the winter when the children were shut in. He believed that rickets was a disease due to bad air.

Dr. L. Emmett Holt of New York said that they had examined a series of breast milks in regard to the salt content and had found that the salts were not deficient during the later months of lactation. The salt content of the later months did not differ from that of the second, third, or fourth months.

Dr. L. E. La Fétra of New York said there was a class of young and feeble infants, especially premature infants, that developed rickets in spite of the best feeding and hygiene. Something seemed to have influenced these babies before birth that produced a tendency to rickets. It was a question whether the food factor or even fresh air entered into the problem. There might be something in the internal secretions that was responsible.

Dr. J. P. Crozer Griffith of Philadelphia said there seemed to be a tendency to rickets in the colored race and Italians. He had observed the disease in a stillborn infant and there seemed to be a hereditary factor. This had been studied by an Italian physician with reference to the past histories of families; he found that with the best of feeding and care children with this inherited tendency developed the disease. He felt sure that rickets was due to something inherited, but he did not know what it was.

Dr. Fritz B. Talbot of Boston stated that with the help of a social worker he had studied one hundred cases of rickets from every point of view and after he was through he could find no definite cause for the disease.

Dr. Joseph E. Winters said that there might be an inherited factor and there was no reason why rickets might not be congenital, but that the underlying causes were those he had spoken of, the diminution of proteins and salts. As to the cases of rickets in colored children and Italians one could not be sure that they were not due to bad feeding, as without the help of a social worker it was impossible to get at the truth in regard to all the irregularities of feeding. If it was a question of atmospheric condition one would not see such cases as the one of which Dr. Gittings had spoken. The fact that children developed rickets on the foods that had been indicated and got over it when put on breast milk was evidence that other factors were subordinate to those involved in the feeding.

The Results of Thymus Extirpation.—Dr. John W. Howland, Dr. E. A. Park, and Dr. R. D. McClure of Baltimore presented this communication. Dr. Parks stated that extensive recent work by Matti, Klose, and Vogt had shown that extirpation of the thymus gland in young dogs gave rise to emaciation and death several months afterwards. Their work showed further that most pronounced changes in the skeleton took place, changes identical with those of rickets in the human being. Van Basch and others had found as a result of thymectomy in dogs transitory changes in the skeleton resembling human rickets, but had failed to find that the thymus gland was essential to life. Some of their thymectomized animals had shown retardation of the development of such extent that at the end of six months they were not much more than one-half the size of the controls, but were nevertheless active, healthy looking, normally formed animals. No changes of a rachitic nature had been found. They felt certain that the thymus gland in dogs was not essential to life and that the changes that resulted from its removal were not of so gross a nature as had been reported in recent work which had come particularly from Germany.

Dr. Alfred Friedlander of Cincinnati said that it was difficult to remove the thymus completely as in certain instances there were accessory thymi and these easily regenerated and took the place of the original thymus and they affected the results of these experiments. Thymectomy in the human being was exceedingly dangerous and there was no absolute indication for doing it. By the operative method the mortality was 33 per cent., while the method of shrinking the thymus with the x-ray had proved simple and safe. They felt justified in claiming that in the x-ray they had a means of treating the enlarged thymus which was just as effective and much safer than thymectomy.

Dr. Isaac A. Abt of Chicago asked what was considered an enlarged thymus, one that produced symptoms or one that appeared large when examined by the x-ray. He felt convinced that examination by the x-ray alone

was not sure. If one could outline the thymus by percussion and there were associated symptoms which were confirmed by the *x*-ray one might be justified in making a diagnosis of enlarged thymus. The only place where the *x*-ray could be absolutely relied on was in the cap thymus; in other forms the clinical evidence was more sure and the *x*-ray only confirmatory.

Dr. E. A. PARK of Baltimore said in reference to the complete extirpation of the thymus that they had looked for rests and believed that their presence had been greatly exaggerated as they had not found them. The operative removal of the thymus ought not to be so difficult. As performed by Dr. Halstead the operation was simple and ought not to be attended with great danger.

The Diagnosis and Treatment of the Late Type of Hereditary Syphilis.—Dr. BORDEN S. VEEDER and Dr. R. C. JEANS of St. Louis read this paper, which was based on the study of 122 cases of hereditary lues at the St. Louis Children's Hospital. Of these 74 belonged to the group usually described as later syphilis, while only 48 were infants under one year with the classical symptoms of rash, coryza, enlarged spleen, etc., which belonged to the early stages of hereditary syphilis. This ratio was the reverse of the figures usually given for the incidence of early and late hereditary syphilis and was due to the inclusion of cases which were not looked upon as luetic before the frequent use of the Wassermann reaction. A wide variety of lesions were encountered and in many instances the lesions were multiple. In every case in which these lesions occurred the Wassermann reaction was positive. The large number of cases with lesions of the central nervous system, 43 per cent., was one of the most interesting features of this series from the standpoint of diagnosis. Among the unusual lesions was an aortitis and a torticollis. Three cases were tested for indefinite pain of obscure origin which had persisted regularly for some time and all gave positive Wassermann reactions, and in all the pain disappeared under specific treatment. The absence of Hutchin's teeth in their cases was very noticeable; of 48 cases old enough to have permanent incisors the teeth were notched in but three cases. They now made it a practice to make a routine Wassermann examination in all cases with chronic lesions of the central nervous system and in many acute cases, and likewise in acute joint lesions and in many cases frequently looked upon as rheumatic. The treatment consisted of a combination of neosalvarsan and mercury. Intravenous injections were used. They preferred the neosalvarsan because it fulfilled essential requirements in children. In acute lesions three or four intravenous injections of neosalvarsan were given with a gradual increasing dosage and then mercury was started in small doses and gradually increased until the patient was taking fairly large doses. This treatment was then interrupted for a short time and again repeated. They had been able to secure but little permanent effect from neosalvarsan and had not observed any advantage from its use in chronic cases of the late type, that was in such lesions as cerebrospinal syphilis or interstitial keratitis that had been present for some time. The Wassermann reaction was stronger in hereditary lues than in any other form of syphilis and hence it was correspondingly more difficult to make negative.

Dr. CHARLES GILMORE KERLEY said it was comforting to hear what had been said in regard to treatment in these late cases of hereditary syphilis. In three cases coming under his observation, one of keratitis, one of periostitis of the tibia, and a third having both keratitis and bone changes, there was no effect from the combined use of salvarsan and mercury.

Dr. SAMUEL MCC. HAMILL of Philadelphia said that Dr. Warthin had been studying the question of the persistence of the spirochete in cases of cured syphilis which had given a negative Wassermann for several years. In such cases coming to autopsy he had found the spirochete in the testicles in nearly every instance and he drew the deduction that syphilis was probably an incurable condition. He had been asked the question, "In cured cases that become reinfected, if the spirochete persisted, what relation had these spirochete to the new infection?" This was interesting in connection with what Dr. Veeder had said in regard to the uncertainty of cure in these late cases.

Officers.—The following officers were elected: *President*, Dr. GEORGE N. ACKER of Washington, D. C.; *Vice-president*, Dr. HENRY L. COIT of Newark, N. J.; *Secretary*, Dr. SAMUEL S. ADAMS of Washington, D. C.; *Treasurer*, Dr. CHARLES HUNTER DUNN of Boston, Mass.; *Delegate to the Association of American Physicians*, Dr. ABRAHAM JACOBI; *Elected to Membership in the Society*, Dr. R. H. WAHL of Chicago, Dr. PHILIP VAN INGEN of New York, Dr. T. DE WITT SHERMAN of Buffalo, and Dr. HENRY F. HELMHOLZ of Chicago.

Place of Meeting.—The next meeting of the society will be held in Cape May, N. J., May 25, 26, 27, 1915.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, Held April 7, 1914.

THE PRESIDENT, DR. SMITH ELY JELLIFFE, IN THE CHAIR.

The Chronic Progressive Cerebellar Tremor.—Dr. J. RAMSEY HUNT said that under this title he would direct attention to a group of cases which he believed belonged to a definite and undescribed *clinical type* of nervous diseases. Three cases of this affection had come under his observation, two of which had been under treatment for a considerable time. The third was of more recent date and would correspond to an earlier stage of the disease. In the outline of the clinical picture, the two advanced cases only would be considered, in which the disease had been constant and progressive over a period of six years. The affection began in one of the extremities, either the arm or leg, as a volitional tremor of the *intention type*, which very gradually increased in intensity. After an interval of a year or more a similar tremor developed in another extremity and progressed in the same gradual manner as in the limb which was first affected. A year or so later the other portions of the body were gradually involved, so that in the course of from three to four years the head, trunk, and extremities presented the clinical picture of a coarse, volitional tremor. The tremor was increased by all movements, however slight, and by any excitement or mental activity. It ceased during sleep, and was always greatly diminished by rest in a relaxed or recumbent posture and usually ceased entirely in this position. Some slight rhythmical tremors of the head, hand, or foot occasionally persisted even during rest in the recumbent position. It was distinctly a volitional tremor, and any attempt at a coordinated movement directed towards some object produced an increase of the shaking and that atactiform tremor which we associate clinically with multiple sclerosis. The tremor movement was slow and coarse, and averaged from three to five vibrations a second. The rate and amplitude were both increased by voluntary movements and by excitement. It was not affected by closure of the eyes. The gait was jerky, uneven, and dysmetric, the smooth harmony of movements being interrupted by coarse irregular tremors of the head, trunk, and extremities. There was no ataxia, either kinetic or static. The equilibrium was easily maintained with the eyes open or closed, even when the whole body was in a state of shaking and oscillation. The speech was slow and scanning, with a tendency to explosive utterance, or it was simply slower than normal. Finer movements of the hands were rendered impossible, so that eating and drinking were difficult, and the handwriting became an irregular scrawl. There was no paralysis: no sensory disturbances, and all the tendon and skin reflexes were present and normal. There was no loss of the perception of weights. The speaker especially emphasized the preservation of the abdominal reflexes, and the normal flexor type of the plantar reflex. The pupils were equal and reacted normally. There was no true nystagmus. Occasionally, when the head tremor was active and it was mechanically checked by holding, the tremor overflowed, and appeared in the ocular muscles. When, however, the eye fixed and followed an object, there was no nystagmus. There were no explosive emotional attacks, nor crises of laughing and crying; no diplopia, no vesical trouble, visual disturbances, nor other signs of multiple sclerosis. The optic discs were normal, as were the other cranial nerves. Memory was intact; there were no unusual states of depression or exaltation, and there were no evidences of mental deterioration. There were no pigmentary deposits of the cornea as have been noted in some cases of the pseudosclerosis. Headaches occurred before the onset of the tremor, and from time to time since. These were chiefly frontal, not of great severity, and not accompanied by nausea or vomiting. There was no true objective vertigo, but in the erect posture, when the oscillation of the head was pronounced, subjective sensations of vertigo and giddiness occurred.

There was no history of epileptiform seizures, cerebellar fits, or vestibular attacks. The Wassermann test for blood and cerebrospinal fluid was negative, and there was no increase of albumin nor cells. The blood was normal, as was the urine, and the general visceral examination was negative, excepting for a small, firm enlargement of the thyroid gland in one of the cases, without symptoms of Graves' disease. There was no history of trauma, nor symptoms indicative of hysteria. Except for the coarse, progressive tremor, which gradually and successively involved one extremity after another, the only other symptoms indicating an organic disease of the nervous system were the following, and these may be referred to a disorder of certain functions of the cerebellum. The adiadochokinesis of Babinski was distinctly present on both sides. There was also a hypotonic state of the muscles, as indicated by flaccidity and softness of the muscular tissue of the extremities, relaxation of the joints and the presence of the Stewart-Holmes sign of hypotonia (failure of the rebound or movement of extension when flexion of the arm has been resisted and is suddenly released.) Mechanical and electrical excitation of muscles was normal. In addition, certain symptoms indicating asynergia and dysmetria were also present, *i.e.* a failure of the harmonious grouping of the movements concerned in a coordinated act. This was especially marked in the upper extremities. While there was no weakness or paralysis of the muscles in the ordinary sense, there was demonstrable an *intermittent asthenia* of a peculiar character, which consisted in the inability to sustain the muscle contractions of a voluntary movement except for a brief period of time. For instance, if the patient grasped the hand of the physician and was instructed to sustain the contraction, even with special effort, relaxation took place in a few seconds and the grip loosened, and another attempt would be made only to suffer the same spontaneous relaxation. This could also be demonstrated in dorsal flexion of the foot and flexion of the arm. The author ascribed this to a defect in the mechanism regulating muscle tonus, and it was, in a way, the reverse of what Babinski had described as cerebellar catalepsy, in which the power of fixation was greatly increased when a limb, by an effort of will, was held in a certain position. The Barany "pointing tests," had been unsatisfactory and difficult of interpretation because of the coarse atactiform tremor on intention. The caloric tests show the integrity of the vestibular apparatus. To summarize briefly, this clinical type, which was considered worthy of differentiation, was characterized by a chronic, gradually progressive tremor, coarse and irregular in character, associated with symptoms of asynergia, hypotonia, adiadochokinesis, and the *intermittent asthenia*, an inability to sustain fixed or continuous muscle contractions. All of these symptoms were referred to disturbance of the cerebellar function. In the differentiation of this condition, the so-called hereditary or essential tremor may be excluded by the absence of a hereditary or family tendency to tremor, by the slow method of progression, successively involving one extremity after another, and by the associated symptoms of a cerebellar affection. The "tremor type" of Parkinson's disease may be ruled out by the disturbance of tonus, which differs fundamentally from the rigidity and hypertonicity of that disease. There are none of the symptoms which would justify a diagnosis of hysteria, a traumatic neurosis or the pseudosclerosis of Westphal. The author realized that in the absence of any pathological support to the contrary, the question of multiple sclerosis was an important one in the interpretation of this group of cases. If the underlying lesion was multiple sclerosis, this group deserved a place among the recognized clinical types of that discase. As, however, all the symptoms indicated a disturbance of the cerebellar function, and were slowly progressive, he would regard these cases as representing a well defined and progressive disease of some portion of the cerebellar mechanism. The clinical type he would designate as the *chronic progressive cerebellar tremor*. It was suggested that such cases had probably been variously classified as hereditary or essential tremor, multiple sclerosis, hysterical tremor, traumatic neurosis and atypical paralysis agitans. The reports of three cases were given.

Insanity Among Jews.—Dr. A. A. BRILL and Dr. M. J. KARPAS presented a joint paper on this subject, which was read by Dr. Brill (see page 576).

Dr. GEORGE H. KIRBY said the paper of Dr. Brill and Dr. Karpas was of special interest to him, as they had for several years past endeavored to collect careful statistics at Ward's Island regarding the different racial types coming into the hospital. Similar data were now being gathered under the supervision of the State Hospital Commission in all the State hospitals. Studies in comparative race psychopathology had always seemed to him important, not only because of their purely psychiatric value, but also because of their practical bearing on some of our sociological and economical problems. It was, for example, important to know that the Italians were bringing in more epilepsy than any other race; that the Irish supplied an enormously disproportionate number of alcoholic psychoses, and that the recently arrived Jews furnished a high percentage of dementia præcox, mania-depressive insanity and feeble-mindedness. While the studies so far made showed that these psychopathic tendencies existed in varying degree among the different alien groups, it was much more difficult to determine if insanity in general was more prevalent in one race of mankind than another. Drs. Brill and Karpas, contrary to certain general impressions, concluded that insanity was *not* disproportionately frequent among Jews as a race, but that in fact, just the opposite was true. Dr. Kirby said he wished to mention one factor involved in this study which he thought threw some doubt on the conclusions reached. To determine the incidence of insanity, one should not compare an essentially immigrant population (such as the Jews in New York) with the native born population. An immigrant population may be variously constituted. It usually contained a disproportionate number of young adults, and the two sexes might exist in unusual proportions. The Italian population of New York had a big majority of young, unmarried men, while the Irish immigration had brought more women than men to this country. On the other hand, the native born population contained from one-sixth to one-fifth of children, and had, of course, a much larger proportion of middle aged and old people than did an immigrant population. The age periods were, therefore, very important in determining the incidence of insanity in any group of people. One reason why dementia præcox and manic-depressive insanity were relatively more frequent among Jews admitted to the hospitals than the native born was because there were relatively more young adults in the Jew population. As the average age of the immigrant population increased, there would be more cases of paresis, and, later still, more cases of arteriosclerosis and senile dementia to record among the Jews. The speaker said that to his mind, more reliable comparisons were those contained in the figures which the authors of the paper quoted from the Russian sociological study. We had there a native Russian population compared to a native Jew population, and the figures were practically equal, the Jews showing only a slightly higher percentage than the Russians. If, however, the multitude of cases of dementia præcox and manic-depressive insanity among the Jews in this country had remained in Russia to be included, the percentage would have probably been even higher for the Jews. In regard to feeble-mindedness, a great deal of the data available indicated that it was proportionately higher among Hebrews than other races. Among all the cases of imbecility admitted to the Manhattan State Hospital during the past four years, 50 per cent. of them were Jews, whereas this race constituted only 21 per cent. of the total admissions. Some studies made in the New York City schools showed a high percentage of Hebrew pupils in the classes for defectives. With ten per cent. of the children of native parentage, there were 40 per cent. of Hebrew parentage: more Hebrew children, in fact, than there were Italian, German, Irish, and negro children combined. At Ellis Island the number of defective Hebrews excluded had been remarked upon; the figures showed that nearly 33 per cent. of all the immigrants certified as mentally defective were Hebrews, whereas this race furnished only 14 per cent. of the total arrivals.

Dr. SMITH ELY JELLIFFE said the general attitude toward any statistical problem was one that was extremely difficult to grasp. Statisticians who followed work of this kind as a profession seemed to feel that the average question could be satisfactorily and definitely solved by figures, and they were apt to ignore certain facts tending to show that such figures, taken by themselves, were of rather superficial importance. Dr. Kirby had emphasized the fact that from the bare recitation of a series of figures we were not warranted in draw-

ing any definite conclusions as to the broader aspects of this problem. Sociologic and economic questions, the transplantation of families, educational factors—all these had to be taken into consideration in trying to solve this problem of the comparative prevalence of insanity among the Jews or other race.

Dr. KARPAS stated that the statistical data in the paper was obtained from the Manhattan State Hospital and the Psychopathic Department of Bellevue Hospital; the former aided them in the study of various forms of mental diseases occurring in the Hebrew and the type of predilection of certain forms of mental diseases; the statistics from the latter prove that the ratio of the Jewish insane to the Jewish sane population was not so high, and since Jews inhabit large cities, New York formed an invaluable source of information for the study of race psychopathology, particularly in Jews. However, he felt that the figures were by no means absolute; but they formed an invaluable index by which one could gauge the insane population and furthermore be guided in future studies along the same line. He also felt that the large number of so-called mental defectives among Hebrews excluded at Ellis Island was not at all conclusive, inasmuch as the medical examiners there were not familiar with the language and racial characteristics of the class of immigrants they were dealing with. One must bear in mind that feeble-mindedness, excluding the well-defined cases of idiocy and imbecility, is purely relative, and before one can diagnose a case of mental retardation, it is necessary to take into consideration the individual in relation to his heredity, environment, and intellectual training.

Dr. BRILL said he realized that the criticisms made by Dr. Kirby and Dr. Jelliffe had some basis, but when one came to investigate the statistics that had been given by various other writers to prove the converse of this contention, namely, that the Jews did contribute more to insanity than any other race, one would find that their deductions were based largely on hearsay, while the conclusions drawn concerning the number of insane Jews in Manhattan and Bronx were based on actual figures. In this paper, Dr. Brill said, they had confined themselves to the question of disproportionate insanity among Jews, and had not taken up the various psychoses, as such; feeble-mindedness, without insanity, was not considered at all, as that class of cases would be investigated and reported at some future date. It was practically impossible, of course, in a study of this kind, to select the cases from the general population at various ages, or to learn how recent or remote their arrival in this city had been. While such a selection might have had some influence upon the results, it would probably have been comparatively trifling, and the percentages would have remained practically unchanged.

Dr. MAURICE FISHBERG (by invitation) said that great care must be taken in interpreting the statistics of insanity—in fact, more discretion was necessary than in interpreting dreams. Ninety-five per cent. of Jews were city dwellers as against only 33 per cent. of non-Jews. Urban dwellers had a higher incidence of insanity, and must commit their mental defectives to institutions, whereas in rural populations the rates of insanity were lower and the milder forms of mental alienation were permitted to roam about. The Jews were engaged in financial and commercial pursuits in much larger numbers than the Christians, and this had an influence in the direction of increasing the number of insane among them. It was, however, impossible to determine the exact proportion of insane Jews in New York, because we had no reliable data as to the actual number of Jews, all the so-called estimates being merely guesswork. As to the statement that 40 per cent. of the pupils in the ungraded classes in the schools of this city were of Jewish descent, the speaker said this did not at all prove that there was more feeble-mindedness among them than among others. Jewish parents were more apt to send their children to school, while other inmigrants often used every possible effort to evade the compulsory education law. Dr. Fishberg emphasized the fact that while studying these problems, one must be extremely careful in the compilation of statistics. While preparing a monograph on the ethnic characteristics of the Jews, he had carefully scanned the literature, which was more extensive than the readers of the paper seemed to be aware, but he could arrive at no positive conclusions. In the official statistics of Austria, Hungary, Germany, and some other European countries there were many data about conditions extending over long periods of years, yet it seemed that the question whether insanity among the Jews was more frequent than among others, and whether there was such a thing as a *psychosis judaica*, or whether certain forms of mental alienation were more apt to occur among non-Jews, had not yet been settled. It all depended, it appeared, on the frequency of the factors instrumental in the etiology of insanity, such as alcoholism, syphilis, precarious occupations, such as banking, mercantile pursuits, etc. That there were no race factors at work was evident from many peculiarities, and this was best illustrated by the frequency of suicide among them. Half a century ago a Jewish suicide was extremely rare, while at present there were more Jews who voluntarily ended their life in Germany and also in New York than others. Ethnic traits did not change within one or two generations. Dr. Fishberg showed that the statistics from Russia, quoted by the reader of the paper, were of no value, because census statistics had never been taken seriously in that country, and, in addition, the Jews there kept their insane at home, excepting in very severe cases, and hence they were not counted in the asylum population. The figures presented by Dr. Brill about conditions in New York were not carefully compiled, and might be interpreted in many ways. More figures were of no value: statistics were always comparative.

The Autonomic Reciprocal Activities of Brain and Viscera.—Dr. WALTER TIMME presented a paper on this subject. He said a decade had now passed since Langley and the English school had contributed to our knowledge of nervous anatomy and physiology a comprehensive plan of the structure and workings of that part of the nervous system which supplied the smooth muscle fibers of the body, the cardiac muscle, and the glandular tissues, and to which they had given the broad term, Autonomic System. This was so-called from the fact that it acted independently of the cerebrospinal system, and still there seemed to be confusion not only in the nomenclature, but also in the interpretation of the many experiments that had been made by various investigators in this field of research. Dr. Timme then briefly sketched the anatomical characteristics of the autonomic system, from which we saw that the viscera generally had a double nervous supply: one from the sympathetic *via* the vertebral and prevertebral ganglia, and the other from either one or the other of the autonomic divisions. These two sets of nerve fibers conveyed a continuous stream of current to the tissues, but from the probability that their end organs in the tissues were different from one another, class for class, their effects upon the viscus were of a balancing character. As a result, the activity of the organ was commensurate with the work that in a given case was required of it, the repair and growth of its cellular elements controlled, the blood supply properly limited; and all these various activities were constantly at work, independent of our will, and, indeed, largely of our consciousness. But such a compensating balancing mechanism was dependent upon many factors other than these, and yet upon factors that were influenced *indirectly* by the will and consciousness, so that if one set of fibers was depressed, the other overacted its part, and the converse. But it would seem that if one set was entirely destroyed, the other, having no physiological antagonist, ceased its influence. We all knew that various associations produced autonomic effects without our will, and it was reasonable to suppose that if we could recall these associations through our will, the same autonomic effects would be produced. Joy caused a rapid heart action; shame was accompanied by blushing; fear sent the blood from the face and lips and dried the mouth; psychical irritation might cause vomiting or asthma or diarrhea, and sexual excitement was followed by erection. Any of these effects could be reproduced by calling up the associations which accompanied their presence at some previous time, so that only indirectly could the will control the autonomic mechanism—a far different matter from the voluntary absolutism over the cerebrospinal. Many attempts have been made to trace anatomically the path of influences from the cortex and other cerebral areas to the bulbar and spinal sympathetic nuclei, and on the other hand the track of the painful and other sensations from the viscera to the cortex, but the sum of our knowledge at present is merely that there exist certain areas in the brain whose stimulation produces certain activities in the viscera. For example, there is a point in the hypo-

thalamic region which, when irritated, produces dilatation of the pupil (Kreidl). The floor of the third ventricle contains an area which partially controls the sugar tolerance; bladder contractions may be called forth by stimulating a part of the hypothalamus; but these results are quite isolated and want further proof. As for the tracts of conduction for these impulses, we simply know that the cervical sympathetic and the superior cervical ganglion were the carriers of the current from the cerebrum and midbrain to the ciliary muscle influencing the tone of the pupil. The other question, the manner of conduction of painful impulses from the viscera to the cortex, was explained by many—Sherrington, Muller, Head and others—as due to the process of "irradiation" from the termination of the afferent autonomic fiber in the spinal ganglion to the spinal afferent nerve in juxtaposition to it, and thence to the cortex. We have now seen in the lowest vertebrate type, the amphioxus, in the mammalian cat and in the human being, based upon embryological development directly observed, upon physiological and pathological experimentation, upon clinically observed facts and upon pharmacological experience, that there was a close relationship between the activity of the brain and that of the viscera, and that in spite of the autonomicity of the one and the primacy of the other, each was complementary to the other in a broad sense, and depended upon it for its own normally functionating existence.

Presentation of Memorial of Dr. Ralph L. Parsons.—Dr. Theodore H. Kellogg, presented this memorial.

Presentation of Memorial of Dr. E. C. Spitzka.—Dr. N. E. Brill presented the following resolution, which was unanimously adopted:

Resolved: That the New York Neurological Society has learned with great sorrow of the death of its member and former President, Dr. Edward Charles Spitzka; that it desires to place on record the expression of its appreciation of the very great value of the services rendered by him to the New York Neurological Society, and to medical science, especially to neuro-anatomy and to psychiatry; And, therefore, it orders that a Minute of this Resolution be inscribed on its records, that a copy of it be sent to the medical press, and that a copy, suitably engrossed, be sent to the family of the deceased.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Illinois State Board of Health.

January, 1914.

ANATOMY.

1. Name the classes into which the vascular system is divided. Give the anatomical structures of each class.
2. Give the three forms of articulations, with one example of each.
3. Name the ligaments of the temporo-maxillary articulations.
4. Name the muscles of the arm, giving the origin of each.
5. What is the longest muscle in the body? Give its origin and insertion.
6. Name the coronary arteries. Where do they arise and terminate?
7. Name the branches of the axillary artery.
8. What does the foramen magnum transmit?
9. Name the lobes, fissures, and arteries of the liver.
10. Where and into what does the great sciatic nerve divide?

MATERIA MEDICA AND THERAPEUTICS.

1. Give the dose, mode of administration, uses, and dangers of apomorphine hydrochloride.
2. Define local anodyne. Name one and describe its use.
3. Name three antacids, give dose and therapeutic indications.
4. Define diuretic, name three and explain use and mode of action of one of them.
5. Classify each of the following according to its therapeutic use: Camphor, morphine, nitrite of sodium, veronal, ergot.
6. Name two drugs which increase the hemoglobin of the blood. Give dose and use.
7. Name two drugs which are alleged to increase the coagulability of the blood. Give uses.
8. Name two drugs which lower blood pressure, giving dose, mode of administration, and uses.
9. Name two diaphoretics and give physiological action of one of them.
10. Name five drugs used for reducing or lowering the temperature in fever, giving dose of each.

CHEMISTRY.

1. Define briefly the following terms: Matter, force, energy, and law of Avogadro.
2. Explain the terms radicle and residue, also reaction and reagent.
3. Name some uses of phosphorus. Give one test for phosphorus in case of poisoning. How many oxides of phosphorus?
4. State chemical action of nitric acid. Complete the following formula: $C_6H_6 + HNO_3 =$
5. (a) Name some of the characteristic properties of hydrocarbons. (b) Give formula for marsh gas. (c) Complete the formula $6Cu + CS_2 + 2H_2O =$

ETIOLOGY AND HYGIENE.

1. Give the etiology of Hodgkin's disease.
2. Give the etiology of cirrhosis of the liver.
3. Give the etiology of rheumatic fever.
4. Briefly discuss the prophylaxis of trachoma.
5. What hygienic conditions should exist in a manufacturing plant employing 3,000 men and 800 women, to protect and main the health of the employees?

PATHOLOGY.

1. Describe the pathology of arthritis deformans.
2. Give the gross pathology of acute lobar pneumonia.
3. Name six pus-producing cocci in the order of their virulence.
4. Describe the pathology of pyonephrosis.
5. Describe the pathology of chronic parenchymatous nephritis.

BACTERIOLOGY.

1. Name some of the important pathogenic diplococci.
2. What are the important pathogenic bacteria found in sputum.
3. Give the bacteriology of syphilis.
4. Give the technique of the Widal test.
5. Describe the blood findings (microscopic) in a case of pernicious anemia.

PHYSIOLOGY.

1. How is heat produced in the body, and how is it given off from the body?
2. Explain dangers of transfusing blood from lower animals into man.
3. What is meant by "physiological leucocytosis" and under what conditions found?
4. Discuss functions of (*a*) proteins, (*b*) carbohydrates, (*c*) fats, (*d*) salts, (*e*) water, all of which constitute food.
5. What physical and chemical changes take place in a muscle during contraction?
6. Give origin and function of the bile.
7. Name parts of (*a*) small intestine, (*b*) large intestine.

ANSWERS.

Illinois State Board of Health.

January, 1914.

ANATOMY.

1. The VASCULAR SYSTEM is divided into two classes: (1) The *blood-vascular system*, which consists of the heart, arteries, capillaries, and veins, and (2) the *lymph-vascular system*, which consists of the lymph glands and lymph vessels.

2. The *three forms of articulations* are: (1) *Synarthrosis*, or immovable articulation, such as that between the two parietal bones. (2) *Amphiarthrosis*, or mixed articulation, such as that between the two pubic bones. (3) *Diarthrosis*, or freely movable articulation, such as that between the humerus and the ulna.

3. *Ligaments of the temporomaxillary articulation* are: External lateral, internal lateral, stylomaxillary, and capsular; with an interarticular disc of cartilage.

4. The *muscles of the arm* are: *Coracobrachialis* (origin from coracoid process of scapula), *Biceps* (origin from coaracoid process of scapula, and upper margin of glenoid cavity of scapula), *Brachialis anticus* (ori-

gin from outer and inner surfaces of shaft of humerus, beginning at about the level of the insertion of the deltoid), *Triceps* (origin from below the glenoid cavity of the scapula, from posterior surface of shaft of humerus and external border of humerus above the musculospiral groove, also from posterior surface of shaft of humerus and internal border of humerus, below the musculospiral groove), and *Subanconeus*, which is really the name of some of the fibers of the lower part and under surface of the triceps.

5. The longest muscle in the body is the *Sartorius*. It arises from the anterior superior spine of the ilium, and is inserted into the upper part of the inner surface of the shaft of the tibia.

6. The *right and left coronary arteries of the heart*, arise near the commencement of the aorta; the right, from the anterior sinus of Valsalva; and the left, from the left posterior sinus of Valsalva; these two arteries anastomose in the substance of the heart. The *superior and inferior coronary arteries of the face* are branches of the facial artery, and run along the upper and lower lips respectively; each one anastomoses with its fellow of the opposite side. The *coronary artery* is also a name for the gastric artery, a branch of the celiac axis, which supplies the stomach.

7. *Branches of the axillary artery:* Superior thoracic, acromiothoracic, long thoracic, alar thoracic, subscapular, posterior circumflex, and anterior circumflex.

8. The *foramen magnum* transmits: The lower part of the medulla oblongata and its membranes, the spinal portion of the spinal accessory nerves, the vertebral arteries, the anterior and posterior spinal arteries, and the occipitoaxial ligaments.

9. The *lobes of the liver* are: Right lobe, left lobe, lobus quadratus, lobus caudatus, and Spigelian lobe (the last three are subdivisions of the right lobe). The *fissures of the liver* are: Umbilical fissure, fissure for the ductus venosus, transverse fissure, fissure for the gall-bladder, and fissure for the inferior vena cava. The *arteries of the liver* are: The hepatic artery, with the two branches into which it subdivides, the right and left hepatic arteries.

10. The *great sciatic nerve* generally divides at about the lower third of the back of the thigh into the internal popliteal and external popliteal nerves.

MATERIA MEDICA AND THERAPEUTICS.

1. APOMORPHINE HYDROCHLORIDE. Dose 1/30 grain (expectorant); 1/10 grain (emetic). It is usually *administered* by hypodermic injection. *Uses:* To produce vomiting, as an expectorant (in bronchitis). *Danger:* Collapse.

2. A *local anodyne* is an agent which, when applied to a part, is capable of relieving pain in that part. Heat is a local anodyne; it may be applied in the form of hot water, by compresses, hot packs, or by immersing the part in hot water; dry heat and steam are also used.

3. *Three antacids:* Sodium bicarbonate, potassium bicarbonate, and magnesia.

Sodium bicarbonate, dose gr. xv, is sedative to the gastric nerves, and is used in dyspepsia, hyperacidity, and acid diarrhea (of infants); it is applied locally in burns, ivy poisoning, and to allay itching.

Potassium bicarbonate, dose gr. xxx, is used in dyspepsia, hyperacidity, gout, and rheumatism.

Magnesia, dose gr. xxx, is used for acidity, sick headache, and mild digestive disturbances.

4. *Diuretics* are agents which promote the secretion of urine. *Three diuretics:* Water, digitalis, potassium acetate. *Potassium acetate* acts as a diuretic by stimulating the renal epithelium, and causing hyperemia of the kidneys, thus increasing the water in the urine. It is used in gouty and rheumatic conditions.

5. *Camphor* is a cardiac stimulant; *morphine* is a hypnotic anodyne and antispasmodic; *nitrite of sodium* is a vascular dilator; *veronal* is a hypnotic; *ergot* is used to cause contraction of the pregnant uterus, also of the muscle fibers in arteries (in case of hemorrhage).

6. *Two drugs which increase the hemoglobin of the blood:* Iron and perhaps arsenic.

Iron. Mass of ferrous carbonate, dose gr. iv; used in chlorosis.

Arsenic. Dose of liquor potassii arsenitis, ♏ iij, to be increased; used in anemic conditions.

7. *Two drugs which are alleged to increase the coagulability of the blood:* Calcium chloride and gelatine. Said to be useful in cases of internal hemorrhage and in hemophilia.

8. *Two drugs which lower blood pressure:* Nitroglycerin and amyl nitrite. *Nitroglycerin* is given by mouth or hypodermically in doses of ♏ 1; *amyl nitrite* is inhaled, dose ♏ 3. *Nitroglycerin* is used in cases of chronic nephritis with high blood pressure, also in anticipated attacks of angina pectoris. *Amyl nitrite* is used in angina pectoris, epilepsy, and cardiac dyspnea.

9. *Two diaphoretics:* Pilocarpine and Dover's powder.

Action of pilocarpine: "Especially stimulates the terminations of the secretory nerves, the first effect being a marked increase of the saliva; also stimulates unstriped muscle generally (with the exception of that of the blood vessels), and particularly in the intestine, causing violent peristalsis. The heart is at first accelerated and then slowed, and the blood-pressure first rises and then falls. The pupil is contracted, and spasm of accommodation occurs. The effects on the central nervous system are mainly depressing; they appear late and are quite overshadowed by the peripheral effects. This drug is the most efficient sudorific known, and with the exception of the diaphoresis its most important effects are the salivation and the myosis. In consequence of the hyperemia of the skin caused by it, the temperature may be temporarily elevated, but the evaporation of the sweat soon produces a decided fall."—(Wilcox's *Materia Medica.*)

10. *Five drugs used for reducing or lowering the temperature in fever:* Acetanilide, gr. iv; antipyrine, gr. iv; acetphenetidine, gr. vij; quinine sulphate, gr. iv; and salicylic acid, gr. vij.

CHEMISTRY.

1. *Matter* is that which occupies space.

Force is that which produces, or tends to produce, motion or change of motion of matter.

Energy is the capacity to do work and also the exertion of doing work.

Law of Avogadro: Equal volumes of all gases, under like conditions of temperature and pressure, contain equal numbers of molecules.

2. *Radical* is a group of atoms which can enter or leave a chemical reaction, and behave in general as a single atom.

Radical of an acid is obtained by the subtraction from the acid of a number of hydroxyls equal to the basicity of the acid.

Residue of an acid is that which remains after removing the replaceable hydrogen.

Reaction is the interaction of two or more substances with chemical union or decomposition; also, the evidences of chemical decomposition afforded by changes in color, solubility, state or shape.

Reagent is a substance used to bring about a reaction.

3. *Uses of phosphorus:* In making matches, rat paste, and phosphor bronze.

Mitscherlich's process for detecting phosphorus: "This process is based upon the property of unoxidized phosphorus of becoming luminous in the dark. The matters supposed to contain the poison are rendered fluid by dilution with water, and acidulated with sulphuric acid. They are placed in a flask upon a sand bath, and the flask connected with a Liebig's condenser, which is placed in absolute darkness. Upon heating the flask any phosphorus present is volatilized, and, condensing in the tube, forms a luminous ring. This reaction is very delicate, and the appearance of the ring is proof positive of the presence of unoxidized phosphorus."—(Witthaus' *Essentials of Chemistry and Toxicology.*)

There are *two oxides of phosphorus*, the trioxide, P_2O_3, and the pentoxide, P_2O_5.

4. *Nitric acid* is decomposed on exposure to air and light or to strong heat; it is an oxidizing agent; it dissolves many metals, forming nitrates.

$$C_6H_6 + HNO_3 = C_6H_5NO_2 + H_2O.$$

5. *Hydrocarbons* are gaseous (the first four members of the methane series), liquid (the next ten or eleven), and the remainder are solid; they are lighter than water and are insoluble in water, but soluble in alcohol, ether, and liquid hydrocarbons.

Formula for *marsh gas* is CH_4.

$$6\,Cu + CS_2 + 2\,H_2O = 2\,Cu_2S + 2\,CuO + CH_4.$$

ETIOLOGY AND HYGIENE.

1. The *etiology of Hodgkin's disease* is unknown.

2. *Etiology of cirrhosis of the liver:* Irritants taken

to the liver by the blood; alcohol, and certain infectious diseases.

3. *Etiology of rheumatic fever* is unknown; probably some diplococcus, staphylococcus, or streptococcus.

4. *Prophylaxis of trachoma:* "The patient and his family must be warned of the contagiousness of the secretion, and impressed with the necessity for keeping the patient's handkerchiefs, towels, wash basin, etc., apart from those of other persons. In schools, asylums, institutions, and barracks, the prevention of epidemics of trachoma is a very serious matter, requiring constant vigilance, careful inspection of every new addition or inmate, and the isolation of trachoma cases so long as the latter are capable of conveying the disease."—(May's *Diseases of the Eye.*)

5. "In addition to the ordinary hygiene of factories and workshops, such as proper space, air, ventilation, water supply, lighting, heating, drainage and plumbing, ordinary cleanliness, and absence of dust, care should be taken that women and children do not work too long at a time or at occupations involving the use of poisonous or deleterious materials; that there are ample toilet and lavatory accommodations, and that these are separate and away from those used by men; there should also be opportunity to sit, and women should not be expected to remain standing for long periods of time."—(Scott's *State Board of Physiology and Hygiene.*)

PATHOLOGY.

1. *Pathology of arthritis deformans:* "The cartilage cells proliferate and burst into the joint, leaving the matrix, which has become fibrillated, looking like coarse velvet or plush. The softened cartilage is worn away at the points of pressure, and the underlying bone becomes hard and polished (eburnated). In spite of this hardness, the bone becomes worn away and perhaps grooved. At the same time there is overgrowth of the cartilage at their margins, which produces 'lipping,' while new bone is formed underneath. These osteophytes may lead to impairment of mobility, or may become broken off and form loose bodies in the joint. The synovial membrane is thickened and its villi hypertrophied. Cartilage may develop in the synovial fringes, and then, if detached, another type of loose body in the joint is formed. Effusion may or may not be present."—(*Aids to Surgery.*)

2. *Lobar pneumonia.* (1) *Stage of engorgement.*—This is the stage of inflammatory hyperemia and edema, and it is characterized microscopically by overfullness and slight tortuosity of the pulmonary capillaries, and by swelling of the alveolar epithelium. The lung is of a dark red color; it is heavier and less crepitant than natural; it pits on pressure; and its cut surface yields a reddish, frothy, tenacious liquid.

(2) *Red hepatization.*—Here there is an exudation of liquor sanguinis and blood-corpuscles. The exuded liquids coagulate within the alveoli and terminal bronchioles, the coagulum enclosing numerous white and a few red blood-corpuscles. The alveolar epithelium is swollen and granular. The lung is now much heavier than in the preceding stage, and is increased in size, so as to be often marked by the ribs. It is quite solid; sinks in water, and cannot be artificially inflated. It is remarkably friable, breaking down with a soft granular fracture. The cut surface has a markedly granular appearance, seen especially when the tissue is torn, and due to the plugs of coagulated exudation-matter which fill the alveoli. The color is of a dark reddish-brown, often here and there passing into gray. This admixture with gray sometimes gives a marbled appearance. The pleura covering the solid lung always participates more or less in the inflammatory process. It is opaque, hyperemic, and coated with lymph.

(3) *Gray hepatization.*—This stage is characterized by a continuance of the process of inflammatory cell-emigration, and by more marked changes in the epithelium. The white blood corpuscles continue to escape from the vessels, and the alveolar epithelium becomes more swollen and granular. The alveoli thus become more completely filled with young cell-forms, so that the fibrinous exudation is no longer visible as an independent material. The fibrinous exudation now disintegrates, and the young cells rapidly undergo fatty metamorphosis. The alveolar walls themselves, with few exceptions, remain throughout the process unaltered, although very occasionally, when this stage is unusually advanced, they may be found here and there partially destroyed. Owing to these changes, the reddish-brown color of the lung becomes altered to a grayish or yellowish white. The granular appearance is much less marked; the solid tissue is much softer and more pulpy in consistence, and a puriform liquid exudes from the cut surface of the organ. This stage, when advanced, has been termed 'suppuration or purulent infiltration' of the lung."—(Quain's *Dictionary of Medicine.*)

3. *Six pus-producing cocci: Streptococcus pyogenes, Staphylococcus pyogenes aureus, Staphylococcus pyogenes albus, Staphylococcus pyogenes citreus Gonococcus, Streptococcus erysipelatis.*

4. *Pathology of pyonephrosis:* "The kidney presents a number of abscess cavities, the intervening parenchyma being pale and tough as a result of chronic interstitial nephritis. Unless there has been antecedent hydronephrosis the pelvis is usually small in proportion to the greatly enlarged and flask-shaped calyces, which constitute the abscess cavities and form the chief bulk of the kidney. Their communications with the pelvis and with each other are narrowed or obliterated, so that they may be regarded as separate cavities. The purulent contents are often mixed with crumbly masses of phosphates. The mucous membrane of the pelvis and calyces is converted into granulation tissue, and, in advanced cases, becomes the seat of ulceration which eats into the parenchyma. The renal blood-vessels are thickened and narrowed by endarteritis, so that there may be very little hemorrhage when the pedicle is divided. The perinephric cellular tissue is converted into granulation and scar tissue, and is frequently the seat of scattered foci of suppuration, and sometimes a large perinephric abscess is found to communicate directly with one of the dilated calyces. The perinephric suppuration may extend into the psoas and quadratus muscles, or into the cellular planes of the abdominal wall."—(Thomson and Miles' *Manual of Surgery.*)

5. In *chronic parenchymatous nephritis* both degenerative and proliferative changes are seen. The tubular epithelium is always more or less affected, showing signs of cloudy swelling, fatty degeneration, desquamation, and disintegration, most marked in the convoluted tubules, but also present in the loops and collecting tubules. The distribution of these changes is usually patchy, giving rise to mottling of the cortex. The lumina of the tubes may be dilated, and contain granular and fatty matters, and hyaline casts, the latter formed by coagulation of exudation in the tubules. The glomeruli may occasionally appear normal, but there is almost always some swelling and hyaline degeneration, together with some proliferation and desquamation of the epithelium, so that they become highly cellular. Occasionally the glomerular changes may be more marked than the tubular; fatty degeneration of the glomerular and capsular epithelium may be prominent, or there may be swelling, proliferation, and desquamation of the epithelium, or both these changes may be combined. The glomerular vessels may be compressed, their endothelium degenerate, and they may be obstructed by leucocytes or by hyaline thrombi, and finally obliterated. Interstitial changes, though present, are not conspicuous, and consist of edema, and scattered foci of round-celled infiltration about the glomeruli and veins. Sometimes hemorrhages are evident in some of the glomeruli and the corresponding tubules. Lardaceous infiltration frequently accompanies parenchymatous nephritis.

BACTERIOLOGY.

1. *Pathogenic diplococci: Diplococcus meningitidis, Diplococcus gonorrhœæ, Diplococcus pneumoniæ, Diplococcus catarrhalis.*

2. *Pathogenic bacteria found in sputum:* Tubercle bacilli, streptococci, staphylococci, pneumococci, Friedlander's bacilli, influenza bacilli, and *Micrococcus catarrhalis.*

3. Syphilis is due to infection by the *Treponema pallidum.* This is a slender spirillum, with regular turns, the curves varying in number from three or four to twelve or even twenty; it is about 4 to 20 mikrons long, actively motile, with a fine flagellum at each pole; it is flexible, hard to stain, and has not been cultivated on artificial media. How it divides is not known. It stains best with Giemsa's eosin solution and azur.

4. Widal's test in typhoid fever "depends upon the fact that serum from the blood of one ill with typhoid fever, mixed with a recent culture, will cause the typhoid bacilli to lose their motility and gather in groups, the whole called 'clumping.' Three drops of blood are taken from the well-washed aseptic finger

tip or lobe of the ear, and each lies by itself on a sterile slide, passed through a flame and cooled just before use; this slide may be wrapped in cotton and transported for examination at the laboratory. Here one drop is mixed with a large drop of sterile water, to redissolve it. A drop from the summit of this is then mixed with six drops of fresh broth culture of the bacillus (not over twenty-four hours old) on a sterile slide. From this a small drop of mingled culture and blood is placed in the middle of a sterile cover-glass, and this is inverted over a sterile hollow-ground slide and examined. * * * A positive reaction is obtained when all the bacilli present gather in one or two masses or clumps and cease their rapid movement inside of twenty minutes."—(From Thayer's *Pathology.*)

5. In *progressive pernicious anemia:* The marked feature of the disease is pronounced oligocythemia. This progresses rapidly, and in ordinary cases the number of red corpuscles sinks to 1,000,000 or less per cu. mm.; at the same time, changes in size (microcytes and megalocytes) and in shape (poikilocytes) make their appearance and reach grades rarely attained in other diseases. Nucleated red corpuscles are always present in some number, and are usually abundant. The largest forms (megaloblasts) as a rule predominate, but in some cases the smaller forms are more abundant. Karyokinetic figures may be found in the nuclei. Polychromatophilia is generally present. The leucocytes may be decreased or normal in number; in the late stages leucocytosis is not uncommon, and it may become extreme. The larger mononuclear leucocytes are usually more abundant than in health, and myelocytes often occur in considerable numbers. In the terminal leucocytosis of pernicious anemia the lymphocytes often predominate.

PHYSIOLOGY.

1. *Heat is produced in the body* by: (1) Muscular action; (2) the action of the glands, chiefly of the liver; (3) the food and drink ingested; (4) the brain; (5) the heart; and (6) the thermogenetic centers in the brain, pons, medulla, and spinal cord. *Heat is given off from the body* by: (1) the skin, through evaporation, radiation, and conduction; (2) the expired air; (3) the excretions—urine and feces.

2. *Dangers of transfusing blood from lower animals to man:* "The serum of certain animals possesses the property of dissolving the red corpuscles of another species of animals. The serum of a dog destroys the red corpuscles of a man; the hemoglobin is dissolved out. The serum, besides its action on the red corpuscles, is also active against the white corpuscles of the same animal, stopping their ameboid movements. The globulicidal action of the serum is related to its poisonous action on microbes. The normal serum of certain animals kills microbes, as the serum of the dog kills the typhoid bacilli. The power to kill red corpuscles and microbes is due to the presence in the serum of a substance, an alexin. In transfusion this plays an important part."—(Ott's *Pathology.*)

3. *Physiological leucocytosis* is an increase in the number of the white blood corpuscles occurring under normal or physiological conditions, such as: Digestion, exercise, after a cold bath, or during pregnancy.

4. *Function of proteids:* Formation and repair of tissues and fluids of the body, regulation of the absorption and utilization of oxygen, formation of fats and carbohydrates, production of energy. *Function of carbohydrates:* Production of heat and energy and formation of fats. *Function of fats:* Supply of heat and energy, supply of fatty tissues, nutrition of nervous system. *Function of salts:* Support of bony skeleton, supply of HCl for digestion, regulation of nutrition and energy. *Function of water:* It enters into the composition of all the tissues and fluids of the body, it moistens the surfaces and membranes of the body, it keeps the fluids of the body at their proper degree of dilution, it removes waste matters, distributes and regulates body heat.

5. *When a muscle is in a state of activity:* (1) It becomes shorter and thicker, but (2) there is no change in volume; (3) there is an increased consumption of oxygen; (4) more carbon dioxide is set free; (5) sarcolactic acid is produced; and hence (6) the muscle becomes acid in reaction; (7) it becomes more extensible, and (8) less elastic; (9) there is an increase in heat production and consequently a rise of temperature; (10) the electrical reaction becomes relatively negative; and (11) a sound is produced.

6. *Bile* is secreted by the liver. *The functions of the bile* are: (1) To assist in the emulsification and saponification of fats; (2) to aid in the absorption of fats; (3) to stimulate the cells of the intestine to increased secretory activity, and so promote peristalsis, and at the same time tend to keep the feces moist; (4) to eliminate waste products of metabolism, such as lecithin and cholesterin; (5) it has a slight action in converting starch into sugar; (6) it neutralizes the acid chyme from the stomach and thus inhibits peptic digestion; (7) it has very feeble antiseptic action.

7. *Parts of the small intestine:* Duodenum, jejunum, ileum. *Parts of the large intestine:* Cecum, ascending colon, hepatic flexure, transverse colon, splenic flexure, descending colon, sigmoid flexure, rectum.

(To be continued.)

Miscellany.

The Motorist's Fuel.—H. Massac Buist notes that the chief factor that controls the present and future price of the motorist's fuel is the ratio of expansion of the world's supplies to that of the motoring movement. When the former exceeds the latter then the price of fuel must become cheaper. An investigation of the world's motor trade at the moment suggests that, as regards private vehicles of the middle and the large sort, the possible rate of expansion has reached something like a fixed quantity. Therefore, as far as these are concerned, fuel production is either going ahead or is about to go ahead of demand. On the other hand, the development of the light car and the commercial motor vehicle has only just begun. The latter would upset all calculations were it not certain that it will soon be run either on other fuel than gasolene or on much cruder spirit than is used for the pleasure car, therefore creating a demand for the residuary product and so making for cheapness all round. But the light car, which is perhaps the vastest field to be entered, will call for the use of the highest grade spirit. The situation of supply and demand would look grave were it not for the fact that the average light car is extremely economical of fuel; a vast number of these machines can be brought into use without making any heavy additional demand by comparison with the increased consumption of fuel when big batches of large cars are brought into use. If one add, therefore, to these facts the all-important one that the requirements of shipping service are all the time creating a demand for residuary products, it may be plainly seen that the price of fuel will probably not rise.—*British Medical Journal.*

Dogs in the Sanitary Service of Armies.—Granjux states that in most European armies the medical corps are provided with dogs that are trained to the task of finding wounded soldiers. Shortly before the outbreak of the present war there was held in Belgium an exhibition at which the wonderful feats of these animals were demonstrated. At Fontainebleau, France, there has been maintained under the auspices of a private national society a so-called "military kennel" at which various methods of training dogs for military purposes have been studied. For instance, these animals have been taught to bring back the cap of the wounded soldier, or in lieu of this something removed from his pocket. In order that these animals may become proficient in their task, it is necessary that they should live with the soldiers for some time, accompanying them on the march, and getting used to the roar of guns and the smell of powder. There can be no question that on the widespread battlefields of today these trained dogs can render a distinct service in helping the medical officers gather in all the wounded.—*Le Caducée.*

THE RELATION BETWEEN THE SURGICAL TREATMENT AND RADIOTHERAPY OF CANCER.*

BY ISAAC LEVIN, M.D.,

NEW YORK.

CHIEF OF THE DEPARTMENT OF CANCER RESEARCH OF THE MONTEFIORE HOME; ASSOCIATE IN CANCER RESEARCH, COLUMBIA UNIVERSITY.

THE malignancy of cancer is due to the infiltrating growth and local dissemination of the tumor into adjacent tissues and regional lymph glands, to the formation of metastases and to cachexia. Of this symptom-complex cachexia appears usually during the late stages of the disease and is frequently absent throughout the whole course of it. Neither is the formation of metastases an early or a constant manifestation of the disease. Metastases occur frequently in carcinoma of the breast, thyroid, prostate, stomach, liver, gall-bladder, pancreas and kidney. In ulcus rodens, epithelioma of the skin and lip, carcinoma of the parotid, uterus, rectum, mouth, tongue, pharynx, urinary bladder, ovaries, intestines, lungs, and mediastinum metastases are rare and occur very late in the disease. In carcinoma of the penis, primary carcinoma of the vagina, and carcinoma of the esophagus metastases are usually absent.

Thus the most important phenomenon in malignancy of cancer is the local infiltrative growth, the local dissemination into adjacent tissues and into the regional lymph glands with the concomitant replacement and destruction of vital organs. Cancer patients frequently succumb either to a fatal hemorrhage caused by an ingrowth of the cancer into the wall of a blood vessel or to an erosion and rupture of the wall of a vital organ adjacent to the growing tumor (stomach, esophagus, rectum, urinary bladder, etc.), before either metastases or general cachexia develop. The ultimate goal of cancer research will always remain the discovery of a specific therapeutic agent, but since, as it was shown above, cancer remains during the greater part of its development a purely local disease, it should be possible to accomplish a great deal with purely local remedies. Indeed in recent years, as will be shown later, the success of such local treatment was very considerable.

Surgical Therapy.—The modern surgical treatment is based on the fact that cancer spreads locally and through the regional lymph glands. It seeks to remove all the normal tissue adjacent to the malignant tumor and into which the latter spreads most frequently. The rule of modern surgery is also to make the incisions in the normal tissue as far from the tumor as safety will permit and furthermore to remove all the regional lymph glands. By these methods, devised on the basis of anatomical and clinical research, brilliant results have been obtained during the last two decades. None the less, operative statistics show that a comparatively small percentage of cancer patients can be cured by surgery alone to-day. Only in carcinoma of the lip the radical cure by the aid of the so-called block dissection of the tumor and the regional lymph glands is as high as 70 to 83 per cent. In carcinoma of the breast Halstead,[1] who is one of the best operators of this condition, reports that 38.8 per cent. of the cases which were operated remained well for three years and over. Since not all the cases examined are operable, probably not more than 30 per cent. of the cases of carcinoma of the breast can be cured by surgery alone. In regard to carcinoma of the uterus Wertheim,[2] the greatest authority on the surgical treatment of this condition, states that about one-half of the cases which come to him are operable and of these about one-half are cured by the operation, consequently about 25 per cent. of the cases of carcinoma of the uterus may be cured by operative treatment. Wm. J. Mayo,[3] who is one of the most brilliant operators in the world, reported recently on 996 cases of carcinoma of the stomach. Of these 344 cases only were operable and of the latter 25 per cent. remained cured five years and over after the operation. In other words about 9 per cent. of cases of carcinoma of the stomach can be cured by surgery alone in the hands of a Mayo and probably an even smaller percentage in the hands of most other surgeons. In all rather less than 30 per cent. of cancer patients can hope to be cured by the aid of surgery alone. It is also safe to assume that there can hardly be expected any further progress in surgical treatment of malignant tumors. The latter are usually situated in close proximity to the vital organs, the injury of which would endanger the life of the patient. There is consequently set a limit to the length to which a surgeon may go in removing the normal tissue adjacent to the tumor. What further progress will be obtained by improvement of diagnosis and the education of the people on the subject of cancer and consequent earlier operative interference cannot be considered here. The fact remains that while operative surgery has accomplished a great deal in the treatment of cancer, further therapeutic progress must depend upon other methods. The whole field of modern therapeutics outside of surgery may be classified in chemotherapy, serotherapy, and physical therapy. The latter method is the most important in the treatment of malignant tumors. Of the different methods of physical therapy employed in medicine radiotherapy is the only one of real value in cancer.

Radiotherapy.—The term radiotherapy in its broad sense means treatment of a disease by the

*Read in part at the meeting of the Brooklyn Pathological Society, January 5, 1914, and of the German Medical Society of New York, February 2, 1914.

aid of different rays. The rays of light may be employed either using the unfiltered sunlight or the artificially produced ultraviolet light, rays of heat, which are used in modern radiotherapy, are obtained through the action of a high potential electric current. This method is called diathermy or thermopenetration. The third class of rays used in radiotherapy are the rays derived from a Roentgen tube or radioactive substances. All these rays are frequently generated through the action of electricity (ultraviolet, diathermy, Roentgen rays), nevertheless it must be clearly understood that radiotherapy is not identical with electrotherapy and that the former means treatment by the aid of rays and not by the aid of electricity.

In the treatment of cancer the rays of light do not play any rôle. As will be shown later, rays of any kind in order to produce an effect on a malignant growth must be able to penetrate into the deeper tissues. The rays of light are absorbed by the superficial layer of the epidermis and do not penetrate any further. The treatment by the aid of the rays of heat, diathermy, is subordinate to other methods of treatment of malignant tumors and will be considered later. The most important method of radiotherapy in the treatment of cancer is the treatment with Roentgen rays and the rays of the radioactive substances.

The rationale of the radiotherapy in malignant tumors must be looked for in the so-called selective action of the rays on the cancer cell. The Roentgen rays and the rays of the radioactive substances are absorbed by the cells of the radiated tissue. Through the biochemical action of the rays the cells become diseased. The injury caused in the cells by the radiations may differ in degree in accordance with the quantity of the rays absorbed. Cells only slightly injured may recover while a severer injury may completely destroy the cell. Every cell of the animal or plant organism is susceptible to injurious action of the radiations. But the susceptibility varies in degree with the cells of different tissues. The cells of malignant tumors are a great deal more susceptible to the action of the rays than the cells of the normal tissues surrounding the tumor. If the rays are employed of a correct quality and in a sufficient quantity it is possible to destroy all the cancer cells in a certain locality and at the same time leave the normal tissues either intact or so slightly injured, that they ultimately completely recover. This quantitatively selective influence of the rays may reach to a depth of at least 3½ cm. Bumm and Warnekros[4] show in their latest publication that it is possible to destroy with the modern methods of Roentgen therapy cancer tissue at the depth of 10 cm. Consequently while the action of the rays is purely local it may well cure certain kinds of even internal malignant tumors. The truth of this selective action was proven anatomically by Aschoff, Hansemann, and many other pathologists and clinicians. But in order to obtain these results correct methods have to be employed.

Technique of Radium Therapy.—Radium was employed in the treatment of cancer nearly since the time the rays were discovered by Becquerel in 1896. The first attempts failed, and the action of the rays did not seem to differ from the action of any other caustic. Dominici,[7] Wickham and Degrais,[6] in France and Krönig and Gaus,[7] Bumm,[8] and Döderlein[9] in Germany showed recently that the failures were due to faulty methods. The radioactive substances emit two kinds of rays. The α and β rays which constitute the greater part of the radiation are called soft rays and have little power of penetration. They are absorbed completely by the superficial layers of tissue, and the quantity absorbed by each cell is so great that all the tissues are destroyed, and the action of the rays is caustic. The hard γ rays represent only about 1 per cent. of the radiation, they penetrate into the deeper layers of tissue and exert the selective action on the cancer cells. It is possible that a small percentage of the hardest β rays have a similar action. With the small quantities of radium used formerly the γ rays had no influence on the tissues. The modern method of radium therapy consists in employing larger quantities of radioactive substances and applying them for a longer period of time. The soft caustic α and β rays, which would be very injurious with the larger quantities of radium used, are filtered off by layers of some heavy metal which absorbs the soft rays. The methods vary with the different investigators, some of them employing extremely large quantities of the substance as high as 800 mgm. of mesothorium at one time. Recently it was shown that with such extremely large quantities the selective action may again be lost and the whole organism of the patient injured. It would lead too far to describe all the various methods employed and the writer will present only his own method of application of radioactive substances.

The radium salt is sealed in thin glass tubes and these placed in a silver tube 0.5 mm. thick. When the surface of the tumor is ulcerated or the radium is placed inside of a tumor, the silver tube is covered only with a thin layer of rubber and then the harder β rays also come into use. But in the majority of cases only the γ rays are used, and for this purpose the silver tube is placed inside of a brass tube 0.75 mm. in thickness. The brass tube is further covered with several layers of photographic paper and cotton in order to protect the skin against the irritating secondary rays which are produced in the metal filters under the influence of the γ rays of the radium. The whole is placed in an aseptic rubber tube. The largest quantity of radium used on a patient at one time is 50 mgm., which is kept continually over the growth for 2, 4, 6, or 12 hours. When the malignant growth is extensive, as in carcinoma of the uterus, the urinary bladder, or the breast, the writer applies the radium for 12 hours of the night every other night until 100 hours of 50 mgm. or 5,000 milligram-hours have been given; after this a recess is taken for four weeks and then if necessary another shorter course of treatment is given. This method of the writer implies the use of a comparatively smaller quantity than is recommended by some clinicians. But the results are quite as satisfactory, while the severe injuries to the adjacent normal tissues caused by the very large doses are avoided. Very recently there appeared an article by Schauta,[10] a noted German gynecologist, in which he states that he has employed radium in carcinoma of the uterus by three different methods. At first he used very small quantities of unfiltered radium and the results were all negative. Then he applied very large quantities of radium for several days in succession, and while the malignant tumors disappeared the patients died as a result of injuries of the normal tissues. At present he employs as a maximum dose 50 mgm. during 12

hours. As a result of this method not a single patient of Schauta died, and 50 per cent. of the patients are clinically cured. His technique is practically identical with the one employed by the writer and reported by the latter[11] on a previous occasion.

Technique of Roentgen Therapy.—The difference between the modern technique of Roentgen therapy and the methods employed 15 years ago is as great as in radium therapy. At present only the hardest rays are employed, the softer being filtered off with metal, usually aluminum. The intensity of the rays employed is also vastly increased. The great susceptibility of the skin to the action of Roentgen rays sets a narrow limit to the quantity of the rays which may be sent through a region. While this quantity is at least 2½ times as great for hard filtered rays as it is for soft unfiltered ones, it is small in comparison with the quantity required to influence a malignant growth. To obviate this difficulty the skin over the area to be treated is divided into several small fields through which the rays are applied. In the deep tissues the rays from the different fields cross and act cumulatively. This method of application is called cross-firing and is also being used with advantage in radium therapy. All the fields may be treated at one sitting and the patient kept under treatment continually for three hours and longer. Otherwise the whole series of fields is divided into three or four parts and treated in as many consecutive days. Then a rest is taken for three or four weeks after which the same series is repeated. A detailed discussion of the differences in the methods employed by the different clinicians would take up too much space and the writer will present only the methods and instrumentation adapted by him for the work.

The writer uses a large coil with an air-cooling device constructed by Reiniger, Gebbert, and Schall of Erlangen, Germany, with a gas mercury interrupter and an additional interrupter (rhytmeur) which breaks rhythmically the current discharging through the tube and allows the target to cool off during the period of the interruption.

For the success of deep Roentgen therapy which is employed in treatment of malignant tumors it is very important to use a hard tube, the penetration of which can be kept constant for a long time. The tubes used by the writer are water-cooled tubes with a small focus tube 10 cm. in diameter with an auxiliary vacuum tube. Water is constantly pumped by an electric pump specially devised by the writer and constructed by Mr. J. C. Goodrich of Montefiore Home which gives more satisfaction than the double reservoir used in Germany. The electric pump obviates the necessity of constantly changing the bottles. Furthermore the water at the target changes more rapidly and consequently cools the latter more efficiently.

The quantity of the rays is read on a Bauer penetrometer and the intensity of the high potential currents discharging through the Roentgen tube is estimated by the milliamperemeter. If the tube becomes harder it is softened by an osmic regulator worked from a distance. All the apparatus can be read and controlled from inside of a lead-lined booth.

Up to the present there does not exist a correct physical method for measuring the quantity of the ray output of a Roentgen tube. The best apparatus to use is the Sabouraud-Noiré pastille or some modification of it, and the Kienboeck photographic strips. The combination of a certain milliamperage of the currents discharging through the tube, a certain penetration of the tube, a given distance between the target and the skin, and a unit of time of exposure indicate the quantity of the rays applied. If all these factors remain constant then the dosage of radiation in a unit of time also remains constant.

Before a new tube is used on a patient it is tried out with a Sabouraud-Noiré pastille. If with the same amperage of the primary current the numbers on the Bauer and the milliamperemeter remain constant, then the time consumed to brown the pastille, *i.e.*, to give a full erythema dose, is also constant. After a few trials a new water-cooled tube usually remains quite constant and the time of treatment indicates approximately the dosage. To cite an instance: A tube under the influence of a constant amperage of the primary current shows 9 on the Bauer, 4 milliamperes through the tube, and it takes three minutes to brown the pastille. If the same can be repeated several times then the tube is seasoned and will constantly give one full dose in three minutes. Should the tube change its character this will immediately show on the Bauer or milliamperemeter. Since two full doses can be safely given of hard filtered rays, such a tube can be used for six minutes on each field of the skin without causing an irritation. In order to be certain that the dose given is accurate a Kienboeck photographic strip is placed over the radiated skin. 10X of Kienboeck usually corresponds to one full dose of Sabouraud, but after six minutes' radiation with the tube described above the Kienboeck may show 15X instead of 20X. This is due to the fact that the measuring apparatus was originally arranged for softer rays than are used at present.

The rays are filtered with 3 mm. of aluminum and a layer of leather; the distance between the target and the skin is 18 cm. The focus tube is inclosed in a box lined with 2 mm. of lead rubber with two windows of double lead glass. The non-radiated surfaces of the body of the patient are covered with lead rubber to protect against the rays.

In Roentgen therapy as in radium therapy the writer's dosage is not as excessive as is used by some German clinicians. In the first place it is hardly necessary or advisable to keep the patient constantly under the rays for three hours. Further, it is not advisable to divide the skin into too many fields, since good results may be obtained by a smaller number of fields. Besides, when each field occupies too small an area the rays will not meet in the deep tissues and a correct cross-firing will not be obtained. Moreover, too excessive a dose may produce severe injuries in the organism. A couple of instances may illustrate the dosage employed by the writer. In postoperative or recurrent cases of carcinoma of the breast the chest is divided into 12 fields, 6 subclavicular, 1 supraclavicular, 2 axillary, and 3 scapular. All the fields are treated in 3 consecutive days, each field getting from 15X to 20X. This constitutes one series of treatment during which the patient gets in all about 200X. The same is repeated in 3 to 4 weeks. In postoperative prophylactic treatment the intervals between the series of treatment is still longer. In carcinoma of the uterus the lower part of the abdomen is divided into 12 fields and the sacral region into 6 fields. The 18 fields are

treated in 4 consecutive days and between 300X-350X is given in one series. Besides this a great deal more than two full doses can be given through the vagina or over an ulcerated area of the tumor.

The Relative Value of Radium and Roentgen Rays.—When Becquerel first discovered the radioactive substances he called his radium tube a pocket edition of the Roentgen tube. This expression very aptly shows their relative position. The biological action of the two kinds of rays is probably very closely analogous, though some investigators claim that there is a qualitative difference in their action on cancer cells. At least cases are on record in which one kind of rays failed and the other kind influenced the growth. The rays of the radioactive substances are a great deal more penetrating than the hardest Roentgen rays which can be produced to-day and the former can be placed close to the diseased area, while the distance between the anticathode and the skin is not less than about 15 cm. In conditions like carcinoma of the larynx, esophagus, rectum, or vagina, the radioactive substances which can be placed within the lumen of the organ are superior to the Roentgen rays. On the other hand, the Roentgen rays can be used over a larger area and are therefore more advantaveous in carcinoma of the breast, or stomach, or in large round-cell sarcomata, lymphosarcomata, mediastinal tumors, etc. Bumm and Warnekros[4] report several cases of carcinoma of the uterus and a case of carcinoma of the lung, which were clinically cured by the aid of Roentgen rays applied through the skin of the abdomen and the thorax. In some of these cases the distance between the skin and the growth was at least 10 cm. In the case of carcinoma of the lung the microscopical diagnosis was made from an excised supraclavicular lymph gland and the result of the treatment was shown on a Roentgen photograph. Furthermore, the Roentgen rays are amenable to technical improvement, and it is possible that ultimately a Roentgen tube will be constructed which will produce more penetrating and powerful rays than the rays of the radioactive substances. At present the best radiotherapeutic results are obtained by a proper combination of both kinds of rays.

Diathermy.—The rays of heat obtained from an external source as well as the rays of light do not penetrate to a greater depth than 4 mm. from the skin. Even when the actual cautery is used the tissue immediately adjacent to the cauterized part is not heated to any appreciable degree. It was shown by Zeyneck,[12] Nagelschmidt,[13] and others that a high frequency current of a sufficiently high amperage and comparatively low voltage causes a rise of temperature of all the tissues between the two poles. With proper technique the temperature of any part of the body or even the whole organism may be raised to any desired degree. Since 1907 when the instrumentation was perfected, the method of diathermy, as this mode of heating tissue is called, is frequently applied in internal diseases. In the treatment of malignant tumors diathermy is employed in two ways. In the first method the cancer tissue is heated to such a degree that the cells are destroyed. This method is also called electro-coagulation and its main advantage over the removal of the tumor with a knife consists in the fact that the cancer cells are destroyed *in situ*, without being severed from the organism, and consequently cannot be disseminated during the operation into the adjacent normal tissue or into the lymph and blood channels. Doyen[14] claims that at a certain temperature of coagulation the cancer cells may be destroyed and the normal tissue remains intact, but such a selective function of electro-coagulation could not be ascertained by other investigators. A radical operation in which the incisions can be done in normal tissue far from the tumor is undoubtedly superior to diathermy. But in inoperable cases where it is desired to remove the greater part of the tumor diathermy is more bloodless than the knife, sharp spoon, or actual cautery and offers less danger of a subsequent rapid dissemination of the remaining tumor cells.

Another method of application of diathermy in cancer therapy consists in heating the tumor to a slight degree and then radiating it with Roentgen rays. It is claimed by Ch. Müller,[15] de Keating-Hart,[16] and others that diathermy renders the cells more sensitive to the Roentgen rays. This method is yet in the experimental stage and in the opinion of the writer the Roentgen rays will be rendered far more effective by increasing their hardness and penetrability than by the aid of diathermy. The technique of diathermy is again different with the different investigators. The writer employs the diathermly apparatus devised by Nagelschmidt and manufactured by Roeniger, Gebbert and Schall. In malignant tumors the writer employs diathermy only in inoperable cases, when the tumor is so large that it is advisable to remove a part of it before beginning the radium or Roentgen therapy. The method employed by the writer is the one recommended by Nagelschmidt, which consists in coagulation of a thin layer of the tumor, removal of the coagulated part; then coagulation of another layer, and so on. In this manner injury of normal tissue with the possibility of secondary hemorrhage or destruction of a vital organ is prevented.

Rationale of the Combined Surgical Treatment and Radiotherapy in Cancer.—Both surgery and radiotheraphy are local methods of treatment, and a general dissemination of the disease or metases in distant organs is at present beyond their reach in the majority of cases, though Kroenig and Bumm reported cases of a metastasis in the lung anatomically cured by radiotherepy. Success in cancer therapy depends upon the destruction of all the cancer tissue in the organism. The advantage of surgery consists in the fact that it removes immediately at one sitting everything diseased. On the other hand it removes with it at the same time a great deal of adjacent healthy tissue. A limit is set to this removal of normal tissue by the fact that vital organs may be injured and consequently the life of the patient endangered. As a result of this a large percentage of cancer patients, as stated above, are inoperable and in a great many of those operated upon there are left microscopical islands of cancer tissue, no matter how radical the operation. These small islands develop subsequently into secondary tumors, and the disease recurs. The main advantage of radiotherapy, on the other hand, consists in the fact that it may destroy such small islands of cancer tissue without injuring the adjacent normal tissue. The disadvantage of radiotherapy consists in the fact that with our present technique it does not reach beyond a certain depth, and while it destroys the upper layers of a large tumor, the lower part may continue to grow.

The great advantage of the combined treatment

is thus self-evident. Surgery must remove the gross tumor whenever possible and radiotherapy must destroy the small islands of cancer tissue which cannot be seen by the naked eye of the operator and which are left behind in the greater number of cases notwithstanding the most radical operation. In other words the treatment of a cancer patient is not complete unless the operation is followed for a certain length of time by radiotherapy. Cases considered to be inoperable, *i.e.* those in which all the cancer tissue cannot be removed and a radical operation cannot be performed, should be operated upon with the aim in view to remove the greatest mass of the cancer tissue. This should be followed by radiotherapy in order to destroy the small disseminated remnants of cancer tissue. A number of inoperable cases of carcinoma have been reported recently which were improved under radiotherapy to such a degree that subsequently a radical operation could be performed. These cases, no matter how rare they may be, show the urgent necessity for radiotherapy in all inoperable cases not only as a most potent palliative measure, which removes the fetid obnoxious discharge from cancerous ulcerations and diminishes pain, but also as preliminary to subsequent surgical treatment. As stated above, at the most only 30 per cent. of all cancer cases remain cured for five years and over after a radical operation. If radiotherapy should change the figure only to 35 per cent. the method of treatment is more than justified. From all the aforesaid it is self-evident that the ideal method of treatment of malignant growth consists at present in the correct combination of surgery and radiotherapy.

Classification of Malignant Tumors in the Light of Combined Treatment.—To facilitate the consideration of the value of combined treatment in the various forms of malignant tumors, it may be well to divide them into groups as is seen on the chart.

(A) *Carcinoma.*

(1) *Superficial:* Seated in and under the skin.	Ulcus rodens. Skin. Lip. Penis. Breast. Thyroid. Parotid Tumor.
(2) *Deep:* Seated in and under the mucous membranes.	Uterus. Rectum. Vagina. Prostate. Œsophagus. Mouth, Tongue, and Pharynx. Larynx. Urinary Bladder.
(3) *Internal:* Seated in and under the serous membranes.	Ovaries. Stomach. Intestines. Liver, Gall-bladder, Pancreas. Lungs, Mediastinum. Kidney.

(B) *Sarcoma.*

The first group of carcinoma is the most easily influenced by the rays. In ulcus rodens and superficial epitheliomata of the skin, radiation undoubtedly accomplishes as much as the knife. It may even have certain advantages, both cosmetic and in the fact that it does not open the lymph and blood channels and thus allow freed cancer cells to enter the circulation. Very favorable results are obtained by radiotherapy in carcinoma of the penis, the breast, the thyroid, and in parotid tumors. But whenever possible, an operation should be performed as a preliminary step to the radiation and as much as possible of the primary tumor and of the involved regional lymph-glands should be removed. But the radiotherapy should follow immediately, otherwise the tumor after a partial operation becomes frequently very malignant and cannot be influenced by the rays subsequently.

Carcinomata of the second group are situated within comparative easy reach of the rays, do not attain very great size, and present good subjects for radiotherapy. As stated above, tubes of radioactive substances may be placed in close proximity to all the parts of the growth. Indeed the most favorable results are obtained in the treatment of carcinoma of the uterus. In a certain number of cases inoperable conditions with involvement of the broad ligaments have been rendered operable by a preliminary radiation. In some of these cases the extirpated uteri did not show any cancer cells on microscopic examination. The other organs of the same group do not yield quite as good results as the uterus. The writer and other clinicians have seen marked improvement in carcinoma of the vagina, the larynx, the urinary bladder, the rectum, prostate, and esophagus. Carcinoma of the mouth, tongue, and pharynx usually do not respond well to radiotherapy. Of the latter conditions carcinoma of the tongue is the most refractory. Most probably the cancer cells in these conditions are unusually resistant to the action of the rays. Generally it must be remarked that cancer cells of the same anatomical structure but originating in different organs or even in the same organs of different individuals may react quite differently to the action of the rays. The work is still in the beginning and improved methods will undoubtedly improve the results. This second group of cases will probably become the true domain of radiotherapy. But for the present in this group of cases radiotherapy should also precede or follow surgical treatment and be employed alone only when the case is completely inoperable. Even then it is advisable to remove the greater part of the tumor with the knife or diathermy and then radiate. Furthermore, the preliminary operations of colostomy, gastrostomy, tracheotomy, etc., are frequently needed in order to facilitate the application of the rays.

The third group of cases of carcinoma is the least amenable to radiotherapy. Still there are cases on record in which carcinoma of the stomach, the large intestines, and even the lungs have been very favorably influenced by the rays. Werner and Kroenig report two cases of carcinoma of the stomach which disappeared under radiation. Whenever an exploratory laparotomy is done and an inoperable carcinoma of the viscera is found, the tumor should be brought if possible nearer to the abdominal wall, so that it may be influenced subsequently by the rays.

Sarcomata are as a general rule influenced by the rays a great deal easier than carcinomata. But here again the best procedure is to remove surgically as much as possible of the tumor, even if the operation cannot be performed radically, and then follow immediately with radiotherapy.

To recapitulate, the advisability of radiation as an only method of treatment of operable cases of cancer, which is advocated by many noted German gynecologists, must be questioned until a sufficient number of years have passed to show the permanency of the reported cures. On the other hand

surgical treatment of malignant tumors is never complete unless it is combined with radiotherapy. All inoperable cases should be radiated, not only as a most excellent palliative measure, but in the hope, small as it may be, that the cases may either become operable or else the disease may be arrested, and the patient may gain months, nay years, of comfortable life. In such inoperable cases when the tumor growth is extensive it may be advantageous to destroy the greater mass of the tumor by the aid of the knife or diathermy and then radiate. In any event the diagnosis of an inoperable malignant tumor should not be the equivalent of a death warrant to the patient.

At present the writer is engaged in experiments on the adaptability of the Coolidge Roentgen-ray tube for therapeutic purposes. It is too early to pass an opinion on the subject. But the tremendous output of the rays from this tube and their uniformity and great power of penetration give a great deal of promise. If we consider further that with the present method of radiotherapy Kroenig and Gaus, and Bumm and Warnekros report cases in which carcinoma of the lungs was destroyed, the results in the near future may be astonishing. The methods of filtration and of protection of both the patient and the operator will have to be greatly improved in order to make the employment of these powerful rays possible. In any event the progress in research on cancer therapy of the near future must go hand in hand with the progress of radiotherapy.

BILIARY SURGERY.*

By JOHN F. ERDMANN, M.D.,

NEW YORK,

PROFESSOR OF SURGERY, NEW YORK POST-GRADUATE SCHOOL AND HOSPITAL.

During the period of time covered by this paper 270 patients were operated upon with thirteen deaths, a mortality of 4 per cent. The majority of these patients were subjected to operative interference upon more viscera than the gall-bladder alone, or the gall-bladder and duct were interfered with, thereby insuring a greater risk as to mortality than individual operations would give.

It is with a view of presenting the causes of death and the operations done that I offer this paper.

Age. This varied from 22 to 74 years.

Sex. The number of patients in whom the sex was recorded was 242; of these 154 were females and 88 were males—rather a sharp contrast to the records of Whittemore of Boston, published in the *Boston Med. & Surg. Jour.*, October, 1913. He reported a series of 595 cases in which there were 441 women and 154 men; almost three times as many women as men.

Type of disease. My records show 54 cases of acute cholecystitis, 34 cases of gangrenous cholecystitis, and 115 cases of cholecystitis not otherwise classified. This series included all varieties, from non-inflammatory to hydrops. There were 6 cases of perforated cholecystitis, 6 non-calculous, 4 malignant, 8 cases of hydrops, and 23 of cholangitis. In addition, acute hemorrhagic pancreatitis, with suppuration or sloughing was observed six times.

The operations recorded were as follows: Cholecystostomy, 125 cases, with 5 deaths. Cholecystectomy, 96 cases, with 4 deaths. Choledochotomy and transduodenal choledochotomy, 5 cases in all, with 2 deaths. Cholecystostomy with choledochotomy, 17 cases, with 1 death. Cholecystectomy with choledochotomy, 27 cases, with 1 death. Cholecystotomy with and without combined operations upon the ducts, 142 cases, with 6 deaths. Cholecystectomy with and without combined operations upon the ducts, 123 cases with 5 deaths.

Here it will be well to note the relative mortality rates in these two types of operation as a prognostic factor in advising their performance. In the so-called lesser mortality type of operation cholecystostomy, with and without combined operations upon the ducts, I report 142 cases, with 6 deaths, a mortality of 4.2+ per cent., while in the graver operation of cholcystectomy, with and without combined operations upon the ducts, I report 123 cases, with 5 deaths, a mortality of 4+ per cent. Attention is also called to the difference in the results after cholecystostomy alone, 125 cases, with 5 deaths, and after cholecystectomy alone, 96 cases, with 4 deaths, in both the mortality being about 4 per cent.

Choledochostomy, singly or combined with operations on the bladder, was done in 49 cases, with 4 deaths, about 8 per cent. If the choledochostomies without additional bladder operations be considered, the mortality in this series is exceptionally high, five choledochostomies of this class being done with a mortality of two, or 40 per cent. These two deaths are easily explained: one occurred on the fourth day from embolism, and the other was due to a compression (interstitial fibrosis) of the liver cells in a patient 65 years old, in whom I opened the common duct, with negative findings, four years after a primary cholecystectomy and choledochotomy for pronounced cholangitis. Added to the cellular change in the liver in this case was a marked nephritis, which was the final cause of her dissolution, as there was almost complete anuria for four days preceding her death.

Secondary operations. Under this term I include those patients who were operated on a second or a third time—not those considered as two-stage operations. I can find the histories of but eight such

*Read before the Surgical Section of the Hartford County (Conn.) Medical Society, April 27, 1914. The greater portion of the paper was also read before the New York Surgical Society, April 22, 1914. I have felt that an additional consideration of the questions of two-step operative procedure, with a brief reference to the *x*-ray diagnosis will be of value.

cases in a series of 270, and these I will mention briefly. All were operated on by surgeons of repute, and I have no reason to doubt that the operations were as complete and thorough as the circumstances permitted. The following case presents a point of interest as to the length of time necessary for stones to grow to some size:

Mrs. B. was operated on six years ago in one of our large hospitals, a cholecystostomy being done. She remained free from pain for about two years. Then all her former symptoms recurred with increased severity, and there were signs of duct involvement. I then operated on her, exposing a very long, adherent gall-bladder containing 33 stones, none of them smaller than a marrow-fat pea. Four stones about the same size were also found in the common duct. A cholecystectomy and choledochotomy were done, together with the removal of the appendix. The patient made a prompt recovery, with no recurrence of any kind up to the present time.

It is but fair to the operating surgeon in this case to assume that in a case of election, as this was, we can preclude the possibility of his leaving 33 large stones in the gall-bladder. Therefore, either these stones were conveyed as fairly large sized ones from the liver into the bladder, or else the growth of stones in the gall-bladder can be very rapid. The common duct invasion must be considered by itself, as this part of the hepatic system was not operated upon at that time. We are all aware of the presence of hepatic stones, and in view of this established fact I advance the above argument as to the possible migration from the liver to the gall-bladder.

The second patient in the series was a young woman who was operated a year ago for an acute gangrenous (?) cholecystitis. No stone was found at the time. She came to me with a persisting fistula, and upon exposing her gall-bladder, a stone the size of a robin's egg was found. This stone, I am quite sure, was overlooked at the first operation. A cure was established in two weeks by doing a cholecystectomy.

The third patient was a physician in whom a cholecystostomy was done hurriedly two years ago in the Presbyterian Hospital for a suppurative condition, and owing to profuse hemorrhage from the surrounding tissues, packing was resorted to. Two years later he again developed marked symptoms. With great difficulty I was able to do a successful cholecystectomy with an appendectomy.

The fourth case was one of my own. The patient was a female, 22 years old, with an acute hemorrhagic pancreatitis. In addition to establishing very liberal drainage, I did a cholecystostomy, removing many stones, some of them the size of a marrow-fat pea. Speedy recovery took place, the drainage wound healing promptly. Only recently or about three years later, I was compelled to explore her for abdominal pains similar to those she had had before her first operation, with the result of finding an atrophied and contracted gall-bladder containing mucopus and an amber-colored stone, entirely different from those originally removed, and about the size of a very large marrow-fat pea impacted in the cystic duct. A cholecystectomy and appendectomy were done, and speedy recovery followed.

The fifth patient was one in whom a rapid cholecystostomy was done twenty months ago in one of our large hospitals by a man of very extensive experience. When I saw the patient, she said she had had a period of eleven months freedom, and then all her symptoms of a stone in the duct recurred. At this time the patient had a temperature of 103.6° and was profoundly jaundiced. An immediate operation revealed a small, purulent bladder and one large duct stone. Upon opening the common duct, no bile escaped; in fact, acholia persisted for fifteen hours, and then only the slightest evidence of bile was present. Twelve hours later, however, bile began to flow in fair amount. In this case a cholecystectomy, choledochotomy and appendectomy were done, and the patient made an excellent recovery.

The last of the series I wish to report was in a Catholic priest of about 40 years who was an athlete and worked hard in his parish. When I saw him, in consultation with Dr. Ludwig Kast, he said he was suffering from pain in his abdomen, similar to that in a previous attack, for which he had been operated upon thirteen months before. That operation, I was informed, was a cholecystostomy and choledochostomy. Conditions arose that demanded an exploration. Cholecystostomy and choledochotomy were again done, retaining the gall-bladder because the common duct was very much thickened (cicatricial), and a chronic pancreatitis existed. The fact was kept in mind that it might be necessary at some future date to do a cholecystenterostomy. This patient for four days went through the most profound manifestations of shock and collapse that it has ever been my misfortune to see, showing all the evidences of a severe toxemia, similar to those observed in acute pancreatitis. It is now about one year since his second operation, and no biliary symptoms have been complained of.

Combined or additional operations other than those of the hepatic system.

Appendectomy. Over ten years ago I called attention to associated disease of the appendix, using the unfortunate term "dual disease" instead of "coincident" or "associated." This association was well illustrated by the second operation upon one of our well-known western surgeons while on a visit to the east a few years ago. I always remove the appendix when the patient's condition permits it, or when the infection can be limited to the gall-bladder zone. In this series I have done appendectomy with cholecystostomy 67 times; with cholecystectomy 49 times; with cholecystostomy and choledochostomy six times, and with cholecystectomy and choledochostomy 15 times, making a total of 137 appendectomies in the entire series, over 50 per cent. Of the above number it happens that the appendix has occasionally been the primary offending member, and the gall-bladder the secondary. One patient with a gangrenous appendix gave a history of gall-bladder trouble for years, she was also two months pregnant. She had an appendectomy and cholecystostomy done without disturbing the pregnancy. In one case a Finney operation for pyloroplasty was done, and in one a gastroenterostomy with choledochostomy. A partial gastrectomy for carcinoma, with cholecystectomy and choledochotomy was done in a woman who was afterwards shown at a meeting of the New York Surgical Society. In this case, three years before, I had done a right nephrectomy, a right oophorocystectomy, and an appendectomy. This patient is living to-day, her second year terminating in two months.

Gastroenterostomy for duodenal ulcer was done in two cases. A gastrotomy for ulcer on the posterior wall of the stomach was done in one case. In one case there was gastric carcinoma. In ten cases there were uterine and ovarian operations not requiring hysterectomy. In one of these there was a large cyst with a pedicle twisted several times. In 17 of the cases the operation was associated with hysterectomy for fibroids. I have found the gall-bladder involved frequently in recent years in this condition, and in my opinion the patient's convalescence is scarcely retarded by these associated operations.

In six of the cases there was an acute pancreatitis in the hemorrhagic, suppurative, or sloughing stages of the disease. Five of these recovered. In all of them a cholecystostomy had been done. One, previously cited, was operated upon recently, doing a cholecystectomy. In one there was a mucous fistula which persisted for two years and then healed spontaneously.

Carcinoma of the papilla of Vater was observed

once. This patient was operated on twice, first a cholecystostomy and subsequently a cholecysterostomy being done. This patient has also been shown at a meeting of the New York Surgical Society.

Perforated typhoid cholecystitis. In one of the cases, a male, during the third or fourth week of his attack of typhoid fever, had a sudden onset of acute abdominal pain, with distention. When I saw him, on the following day, he was comatose and a rapid exploratory operation for suspected perforation of the bowel revealed two large holes in the gall-bladder, with profuse peritoneal soiling with purulent bile-stained material. The wound was rapidly drained and packed and the patient was returned to bed in 11 minutes, quite moribund. He was unconscious for seven weeks, but finally recovered.

In February, 1903, I presented the subject of "Primary Typhoidal Perforations of the Gall-bladder" at a meeting of the New York Surgical Society recording the history of a female patient 46 years old, with a successful outcome. In preparing my article at that time I collected the then available statistics of this complication of typhoid and found that, my own case included, there were thirty-four in all, and that of these, four had recovered.

Hydatids. Two patients with this complication have been operated on by me in the past two years. In one where I did a cholecystectomy and choledochostomy, the hydatid was about the size of a hen's egg. It was located in the liver at the sulcus of the suspensory ligament and was easily excised intact with secondary suture of the liver. My second case of hydatids will be recorded under the fatal cases.

I have had one case of acute phthisis associated with cholecystitis gangrenosa. In this I did a successful cholecystectomy, but within less than one year jaundice occurred and colic recurred. A further operation was then deemed inadvisable. This was some three months ago and I have not seen the patient since.

Hemolytic jaundice. This patient was a young man of 20, upon whom I did a cholecystostomy for suspected cholecystitis, followed in six months by a splenectomy. The latter operation was done about three months ago with entirely satisfactory results.

A subphrenic abscess occurred in six of my series with one death. This fatal case is the same one recorded under complicating hydatids.

Transduodenal operation. This operation has been done by me three times in my career, successfully in each instance. With the advent of the Blake forceps I feel the necessity of this procedure has been passed, as with the ordinary choledochostomy opening we can, with this instrument, grasp and remove, with or without crushing, all stones, even when well impacted in the papilla of Vater.

Morbidity and secondary operations. These questions cannot be reported definitely or satisfactorily until some clearing-house method is established of reporting to the original operator the patient's condition and the necessity for further operations, etc. When some such method is employed data of value to all, particularly to the prospective patient, can be advanced.

Deaths. In 1910, out of a series of 43 of these cases, no deaths occurred.

In 1911 there were 54 operations, with four deaths. The first of these was a widow of 50 with general streptococcemia. A cholecystostomy was done in the hope that some benefit might follow, particularly as the patient was slightly jaundiced. Death resulted from a septic endocarditis, the patient surviving the operation by several days. It is possible, indeed, more than likely, that in this instance an unnecessary operation was done, but it is not probable that it hastened the patient's death.

The second death in the series was that of a Polish Jewess, well advanced in years and enormously fat, with a double inguinal and an umbilical hernia, all of large size. She came under my care with a general peritonitis, her illness dating back about ten days. A fairly clear gall-bladder history was obtained. Operation revealed a large perforation in the gall-bladder, with pus and bile free in the peritoneal cavity. This patient was apparently on the road to recovery when a fatal pneumonia supervened.

The third case was one of acute hemorrhagic pancreatitis in a man, 55 years old, with an illness of ten days' duration. He was moribund when a cholecystotomy was done and many stones removed. Death occurred within thirty-six hours.

The fourth case was that of a man over sixty upon whom a choledochostomy and cholecystotomy were done. Death followed on the seventh day from embolism, while he was engaged in a fierce argument with his son, a physician, about the necessity of continuing his special nurses.

In 1912 there were 63 recorded operations, without a death. In 1913 there were 78 recorded operations, with 6 deaths, two of them after cholecystostomy.

The first case was that of a man 38 years old, who had dilated veins and varicosities to such a degree that merely rubbing the exposed mucous surface of the gall-bladder would be followed by a profuse hemorrhage. The veins in the vicinity of the pylorus and stomach were three-quarters of an inch in diameter. Death occurred on the fourth day and was attributed to acute gastric dilatation.

The second case of this series was that of a man, 55 years old, with cardiac myositis, which proved fatal. In this case the operation showed a perforated gall-bladder, with a mural abscess containing air.

The third case was that of a woman of 60 where death followed a choledochostomy done erroneously for supposed duct obstruction which proved upon microscopical examination of the autopsy specimens to be a cell destruction by interstitial hepatitis. This patient had been operated by me some three years before for a profound streptococcus cholangitis. A cholecystectomy and choledochostomy were done, with a stormy convalescence and prolonged drainage, followed by a condition of health far better than she had enjoyed for fifteen years. After three years she had a sudden recurrence of her jaundice, and at the second operation the bile flowed perfectly clear and in fair quantity. While apparently progressing favorably, an acute nephritis supervened upon a chronic renal impairment, with fatal result.

The fourth case was that of a man, 55 years old, with a suppurative cholecystitis, a percystic abscess, empyema, and a suppurative hydatid cyst. This patient had suffered from jaundice, with an intermittent temperature, for seventeen days, and was much emaciated. Operation revealed a perforated gall-bladder, with two well localized abscesses, one on each side of the gall-bladder. Owing to the

patient's serious condition, drainage only was done. Several days later, as the temperature still remained high, an exploratory aspiration of the chest was made and eight ounces of purulent fluid withdrawn. The following day a section of rib was made, and a few ounces of murky fluid evacuated. It was then seen that what had been regarded as a typical empyema was a lesion involving the dome of the liver, and upon puncture, over a quart of hydatids in most foul *Colon communi* pus was evacuated. Death followed from exhaustion about two weeks after the operation.

The fifth and sixth cases, one a man 55 years old, and the other a woman of 74, both died of nephritis, the first after a cholecystectomy and the second after a cholecystostomy.

In 1914, up to April, there is a series of 26 cases, with three deaths. The first was that of a woman with well advanced symptoms who died from nephritis after a cholecystectomy. The other two patients were males, aged 55 and 57 years, respectively. The first was much emaciated and deeply jaundiced, with skin the color of mahogany. A choledochostomy was done and the patient died four days later from an embolism. The second patient had already been operated for prostatic enlargement and his urine contained the *Bacillus coli communis*. There was an intermittent temperature of the Charcot type. A cholecystectomy and choledochostomy were done, showing evidence of a pure streptococcus infection. The patient's temperature dropped from 103.6° to 99°, he developed a generalized maculopapular eruption (septic infarcts), and died on the eighth day.

With the citation of the fatal cases, as given above, I cannot feel that I have been responsible for a single death by doing any additional operative procedure, as it will be observed that of the thirteen deaths, but two of the patients had any complicating disease. Of the thirteen deaths eight were in males. The fourth death in 1911 was the result of pancreatitis, and was reported as such in a paper on "Pancreatitis" published during the present year in the *New York Medical Journal*. The other, the fourth patient, who died in 1912, required the operations to which he was subjected excepting the one for supposed empyema, as I am satisfied that my exploring needle must have tapped his hydatid abscess. Nevertheless, the suppurating hydatids were best approached through the transpleural route.

As a conclusion based upon these statistics, I am inclined to perform cholecystectomy more frequently than heretofore.

Two-Step Operation.—This is a rarity with me—in fact, has been considered in only a few instances when a rapid cholecystostomy for gangrene, etc., was indicated.

These cases in many instances resolve thoroughly and do not invariably return for further operation. Several instances of this type can be cited, one in particular.

A sea captain, 74 years old, with a history of recurring attacks of gall-bladder colic, was seen by me through the courtesy of Dr. Walser, of Staten Island. At this time he gave a history of acute cholecystitis of some ten days duration—the signs and symptoms, when seen by me were those of gangrene with possible perforation. The patient's condition was such that a hurry operation only was feasible. The abdomen was opened, with findings of a gangrenous and perforated gall-bladder filled with calculi. The escaping, purulent bile was limited by omental adhesions. A large tube with iodoform drainage was installed. The patient, during delirium evidently due to a deficiency in his urinary output, jumped from the second-story window of the hospital, alighting upon his heels and fracturing both ossa calcis. Upon being returned to his room he was free from delirium, remained so, and made a perfect recovery from both his gall-bladder involvement and the fractures. He finally died some four years later of pneumonia.

This citation is no argument that these patients all recover as, had he been a young man, his expectancy of life would have been far greater and recurrence of gall-bladder symptoms might have been observed.

I do not believe in the two-step operations as advocated by many, but would heartily indorse it only in those instances when a primary operation in the ultra-serious patients is done for drainage, or realizing that obstruction is present or still exists—as in the case of a physician in Bridgeport whom I recently operated upon.

When first called to see him on a Sunday afternoon his condition was found to be very grave, due, in all probability, to a cholecystitis gangrenosa, giving at the same time a set of symptoms indicative of common duct stone or pancreatic obstruction. Upon opening the abdomen a large, distended, acutely thickened gall-bladder was exposed, with profound involvement of his pancreas. It was deemed advisable to drain the gall-bladder only, and defer secondary operation to some later day, as it was suspected that the pancreas might be malignant. This was done, with a prompt recovery and closure of the cholecystostomy wound. In view of his recovery and gain, the malignant suspicion became doubtful, when suddenly he reported a profound attack of pain and jaundice. Such attacks occurred several times—he then concluded he was ready for his second operation. This was done some five or six months after the first. The findings were highly pleasing, although difficult to remove, owing to the adhesions from the previous attacks and operation. The pancreas had resumed normal size and a single stone was found in the common duct. The appendix also was removed. He has made a most satisfactory recovery, gaining quite a number of pounds during the year now passed since his operation.

Such procedure has been carried out by me on several occasions—one of them being another physician in whom, at the second operation, I did a successful transduodenal operation.

Obstruction Due to Gallstones.—I have operated five times for this condition—four of the patients unfortunately so far gone (fecal vomiting, etc.) at the time of operation that recovery was impossible.

The fifth case was that of a widow, 74 years of age, with a clear history of repeated attacks of gallstone colic, in whom an acute attack, suspected of being appendicular, was observed by several physicians. When I saw her, she was so tender in the right iliac zone as to mislead me into diagnosticating a gangrenous appendix. Operation was done under great difficulties at 1 A. M., an acetylene lamp from an automobile being the improvised light—an assistant with an infected hand giving ether—myself and a green nurse doing the operating in a ponderously fat old lady. The incision through the peritoneum was followed by a coil of ileum popping into the wound; the coil was felt to contain a large hard substance obstructing the ileum about 4 inches from the ileocecal valve; in addition it was observed by the palpating fingers that there was a tumor of the right ovary the size of a large lemon, and the suspected appendix was but a chronic one, quite large and adherent. The gall-bladder was not palpated, owing to the patient's profoundly depressed condition. A rapid enterostomy, with extraction of a stone the size of a large walnut, was done, the ovarian

tumor and appendix were removed, and a drain was placed in the peritoneal cavity for forty-eight hours. A speedy recovery was effected. About two years later she again suffered an attack of gall-bladder colic, which rapidly subsided. She has now gone by her seventy-seventh year, and for over one year no further trouble with the gall-bladder has been evident.

Trauma.—I cannot close this discussion without citing the history of a patient upon whom I operated recently, bearing upon trauma as a factor with a distinct medicolegal aspect.

The patient, a young man, was brought to me with the history of being struck, a few days before, in the upper right abdomen by a kickback from a piece of wood that he was sawing with a circular saw, in the factory of his employer. His condition was such that no careful history of his previous condition was taken. An operation for cholecystitis or possible rupture of the gall-bladder was done; a gall-bladder with cloudy bile was opened—the terminal fluid being milky white. Pathological examination failed to reveal pus organisms, but clinically the patient evidenced a typhoid chart and upon examining him for typhoid, Widal was found positive. The patient was, or is now in the hands of his attorney, trying to prove trauma as the cause of his cholecystitis, while we in a more careful history have obtained the facts that he was ailing for quite some time before he was struck by the piece of wood.

A word about the *x*-ray diagnosis. Recently Pfahler of Philadelphia, in the *Journal of the American Medical Association*, states that although he had 74 per cent. definite evidences of stones by the *x*-ray, he felt that 50 per cent. in the hands of himself and other radiologists would be a fair average. That to show gallstones the greatest care and repeated exposures are necessary. Also that lime salts must be present with cholesterin to give a shadow.

THE DIETETIC TREATMENT OF CHILDREN DURING THE SECOND PERIOD OF LIFE.*

By CARL G. LEO-WOLF, M.D.,

BUFFALO, N. Y.

During the last two or three decades the physiology of metabolism has been brought more and more on a scientific basis, and we have been taught the "why and wherefore" of many an old and tried dietary rule, but we have also seen many a cherished theory exploded, many a time-honored custom discarded, many a pet measure proven to be contrary to the laws of nature.

In order to understand the better the dietetic treatment of children during the second period of childhood, that is during the period of first dentition from the end of the first to the seventh year of life, it will be necessary for me to give you a brief recapitulation of the demands on the part of the child's body for food during this time.

First of all I must state that we must have a clear understanding of the fact that there is a vast difference between the demand of a child for food and its consumption of food, as it is only too well known by us pediatricians that children during this period of life are, as a rule, overfed. This condition usually arises at the time of weaning. Hardly any mother knows how much her infant is getting at the breast, and when she weans the little one she attributes every crying spell to hunger, and in giving more food she adds to her mistake; thus only can we explain the large number of cases of digestive disturbances at this time and the fear of mothers of weaning their babies during the summer months when overfeeding bears its evil fruit. Whenever possible the physician should superintend the weaning and he should determine by careful weighing, both of the infant and the food, how much the child is getting and what progress it is making.

What then are the demands of the child for food? The answer cannot be given offhand, but must be given separately for each age and also for the respective weight of the child; and it is best here to remember Rubner's statement that metabolism and demand for food correspond to the surface of the body, but that there is no essential difference in the metabolism of the adult and that of the child, except that the one is growing and the other is not.

The child lives almost exclusively on fat and carbohydrates, from which it produces the necessary heat; it reserves the ingested protein for growth and it will therefore be able to get along with very small amounts of nitrogenous food. The demand of the child for protein ranges according to age and weight somewhere between $7\frac{1}{2}$ and 20 grains per pound of body-weight, *i. e.* an average of about $13\frac{1}{2}$ grains per pound. Not more than 10 per cent. of the total calories should be supplied by proteins, and less than one-half of these should be derived from animals.

Now as to the proportions of carbohydrates and fats, these must make up the other 90 per cent. of the calories, at first, that is in the beginning of the second year of life, in the proportion of 40 per cent. of carbohydrates and 50 per cent. fat; but with growth this proportion changes in such a manner that the carbohydrates will prevail more and more. A safe rule to remember is the following: no less than one-fourth the necessary calories should come from fat, and the proportion of fats to carbohydrates should be such a one that the child's food contain not more than 6 or 7 parts of carbohydrates by weight to one part of fat.

As to the salts in the food, this question is just now being worked out in the different laboratories and we are learning more about this daily; enough at present to say that some salt is a necessary addition to the child's diet, but not more than 1 grain per pound of body-weight daily, as every additional grain of salt has to be excreted and therefore creates a demand for more water; an excess of water in its turn will carry away not only the superfluous solium chloride but other salts as well which were not in excess and which will thus be lost to the body.

After these general remarks you will ask me what shall we give our little patients to eat and how shall we give it?

You know that I am an apostle of rare feedings and long intervals in infant feeding, and I hold the same views about later life. True, at the time of weaning it is best to adhere to our well-tried five feedings daily at four hours interval, nothing naturally being given at night; but as soon as possible we should leave out the afternoon meal, the one corresponding to the afternoon tea, and later also the second breakfast, so that the child gets one-quarter each of its daily allowance at breakfast and supper and one-half at dinner, the heaviest meal coming best in the middle of the day followed by a nap. I have just stated that I consider myself an apostle of long-interval feeding in children, but that does not mean that I am a crank on this

*Read before the Lake Keuka Medical and Surgical Association, July 9, 1914.

subject. I realize as well as anybody that we must individualize and I know that some children have to have their meals more frequently; but I also know that frequently children will have a much better appetite and will do much better on three square meals a day even at from two to three years of age. We must, however, not attempt to fool ourselves or let us be fooled by the mothers: we must call everything given to eat and every glass of milk between meals a meal.

In what form should we then give the necessary 30 calories per lb. to a child during this second period of life?

This forms the transition from the lactivorous organism which is living, at least when it gets the food destined for it by nature, on a homogenous material to the omnivorous organism which man represents living on heterogenous material.

We must get away from the old idea which is still too deeply rooted in the minds of the laity as well as of many physicians that milk, animal milk, is the ideal food for children after the completion of their first year of life; it is a poor enough substitute for mother's milk during infancy, why then should we wean a child from the mother's breast to give it another food destined for infants, infant cows though they be? Does not the development of the teeth at this time indicate clearly enough the nature of the food to be given forthwith?

Many an originally healthy set of teeth is spoiled through lack of use at this early age and by the continued feeding with liquid or semi-solid food. The solidity of the food should be determined by the stage of eruption and the number of the teeth.

Do not misunderstand me, please. I do not want to be quoted as saying that milk is bad for small children. I do state, however, that milk as the exclusive or even principal food for small children is bad, but it does constitute a very valuable addition to the child's dietary, though it is best, especially with advancing years, to banish it from the menu for dinner.

Broth, which used to be considered one of the mainstays in the bringing up of young children, makes a good recipient for the farinaceous foodstuffs, but should not be given by itself, for it is too voluminous in proportion to its nutritive qualities, as it contains only 7 calories per 100 c.c.; it also is too rich in salts, containing 1.5 per cent.; its value as a food is therefore determined by what we cook in it. Strong broth and beef tea are stimulants and as such have no more place in the dietary of the healthy child than has alcohol.

During the second year of life when milk is still given in considerable quantities this will furnish most of the proteins, some of which will also be supplied in the cereals we give now; the salts will be ingested in the tender young vegetables which we allow at this age and in the fruit. Of the vegetables the best for this age are spinach, carrots, lettuce, potatoes, Spanish chestnuts; of the fruits apples, pears, oranges and bananas, these latter cooked either as vegetable or as fruit. I am also a great believer in the leguminosæ: dried beans, peas and lentils, and also soy-bean flour. As the young vegetables are given principally for their salts, we must see to it that the child really gets these; in the ordinary household the water in which the vegetables have been boiled, which then contains most of the salts, is thrown away and the child is thus robbed of a most essential part of its food. We must tell this to the mother and teach her to boil down this water and to add it again to the vegetables in straining them.

For the teeth nothing is better than to give the child dry toast made in the oven (not the soggy kind), zwieback, Holland rusk, crackers and graham wafers.

During the next two years we may give occasionally, but by no means regularly, an egg or some minced meat; we can also allow the coarser vegetables such as the different kinds of cabbages, cauliflower, parsnips, turnips, and asparagus; of the fruits those with pits and the berries with the seeds strained out; the child may now get bread, ordinary toast and rolls.

After the age of four the child may eat at the family table, especially as it may now be allowed to chew its meat, and it is safer to have it do this beneath the watchful eyes of its parents, as it might otherwise acquire the pernicious habit of bolting its food; it may get all kinds of vegetables and fruit, and the daily allowance of milk may be still further cut down, though this will hardly be necessary, as many children refuse to drink milk at this age.

So much about the diet of the healthy child during the second period of its life. We will now consider briefly what we can accomplish with the dietary treatment of sick or weakly children of this age.

I shall not speak of those conditions due to affections of the alimentary canal and its appendages, to diseases of the kidneys, or to the different forms of infection, but I shall confine myself to constitutional disturbances such as we find so frequently in these children and which are caused by faulty feeding during infancy, and will therefore be found most frequently in unnaturally fed children, or which may be due to some inherited constitutional peculiarity or inferiority.

Many a child which had been looking quite well at six months may look pale and pasty at the beginning of its second year. This is due to an anemia consequent upon the lack of iron in milk, for there is less than one-third of a grain of iron oxide in one quart of cow's milk, and even less in woman's milk. This anemia will readily yield to the feeding of green vegetables and it is to prevent this condition that we now recommend the administration of fruit juices and vegetables during the second half of the first year.

In rickets the treatment should also be principally a dietetic one, and here again a judicious mixed diet with plenty of fresh fruit and vegetables will accomplish a great deal more than overfeeding with milk.

Moeller-Barlow's disease, or infantile scurvy, is amenable to dietetic treatment only. The easily assimilated salts of the vegetables and fruits and perhaps also their acids will succeed in conjunction with raw milk where medication has invariably failed.

Spasmophilia, which causes such symptoms as laryngospasmus, tetany and nervous overexcitability can be easily controlled by taking away all cow's milk from the child's dietary and feeding it on a diet containing vegetable proteins only, as the animal proteins seem to cause these conditions. After a week or so we can carefully add cow's milk again in small amounts; in fact, we can use this as a control of our treatment.

We now come to that most interesting condition, the exudative diathesis, attention to which has been called especially by Czerny, and about which a great

deal of discussion is going on at the present time. This consists in manifestations from the lymphatic system, an increased activity of which causes hypertrophic swelling of the lymphnodes and an overproduction of lymph; this gives rise to glandular swellings, exudations on the skin, and frequent as well as refractory catarrhs of the respiratory passages. At the same time that these symptoms of constitutional disturbance are most pronounced we find in the exudations and also in the blood a tremendous increase of the acidophile cells.

What this condition really is has not yet been settled; for us it suffices to know that it is of very frequent occurrence, that it runs in families, that it can be cured or at least considerably improved, and also prevented by dietetic treatment. The importance of its early recognition and treatment will be readily understood if we consider that the asthma which incapacitates one of our adult patients so frequently from work and which makes it so hard for him to find a job is due to the same inherited condition which produces adenoids and enlarged tonsils and swollen glands in the neck in his older children, the same which produces the thick crusts in his eczematous baby, and which gives this baby the frequent attacks of bronchitis.

As I have just stated, these conditions can be influenced by diet, by giving the child the lowest possible amount of food, and especially of the animal proteins, on which it can exist, even if its weight remain somewhat below the normal. With dietetic treatment we shall not only be able to influence the pathological conditions after they have appeared, but shall be able many a time to prevent their appearance in the younger children in families where the older ones have had these symptoms. Who will contradict me if I state that we may be able to prevent asthma and chronic bronchitis in the adult by changing the diet of the young child?

Formerly we would have treated these cases with medicine, the so-called symptomatic treatment, which is nothing but a poor excuse for not finding out what is really the matter with a patient, and if we had changed the diet at all it would have been to order a so-called "strengthening diet," one with plenty of milk at meals and between meals, and then some more, and rare roast beef or steak, not to forget the eggs in all forms from raw ones up. What would have been the result of this "strengthening diet"? The child would perhaps have had constipation or stubborn diarrhea, or both alternately, its complexion would have been yellowish, it would have had a tendency to pruriginous eczema, its sleep would have been poor, it would have developed neurotic symptoms, and if we had taken the temperature regularly we would have found continuous subfebrile temperatures.

Now we put these children on a diet which is almost exclusively vegetarian, and I may state here that in this I go even farther than Czerny and his school, with the result that the children remain thin but well.

In conclusion I would say that the dietetic treatment of children at this as well as at any other age is not an easy matter.

In the first place it is hard, even in the so-called better families, to find out what the child really eats, not what it is given, as part of this is usually spoiled and wasted. We must insist upon getting every information as to kind, amount and preparation of the food.

And second it is very hard to make the laity understand the importance of our dietary. We must therefore make it a rule to be most exact in giving our instructions as to the time, the amount, and the preparation of all and every food and drink, and the less we leave to the mother or attendant the better will be our results. True that in order to do this we must realize ourselves what we want to accomplish, and by what means. I am convinced that a thorough knowledge of cooking is one of the essentials of success.

Third, we have to contend with prejudice and ignorance, and we must strenuously resist the meddling interference of others. We must therefore be most deliberate in our directions, which should be invariably in the form of a written prescription, but we must not be inconsiderate and forgetful of individual differences, of idiosyncrasies, and of innate physical or psychical aversions. We must take into account geographical as well as racial differences, even local tastes and customs. We will always succeed if our diet is strictly adhered to, and if we cannot accomplish this in the home then we will be able to do so in the hospital or in a well-regulated sanitarium.

Lastly we must not be oblivious of the social conditions of our patients, we must realize that for a large percentage, if not the majority, of our patients we must try to provide the necessary diet at the least expense, and we must always avoid prescribing anything which is expensive and which we could get more cheaply in some other form, even if its name should not be quite so high sounding nor its advertisements quite so attractive. If we will only pay some attention to this we shall find that it is not at all difficult and we should retain the good will of our patients.

It now only remains for me to acknowledge my indebtedness for a considerable part of the subject matter of this paper to the chapter on nutrition after the first year in Pfaundler and Schlossmann's textbook on the diseases of children, which I had the pleasure of translating, and also to the collected essays of Prof. Dr. Heubner.

481 Franklin Street.

HYPERTHYROIDISM.*

By I. Willis Ballard, M.D.,

Opelika, Ala.

The history of the surgical treatment of disease of the thyroid gland has been an extremely meager one until within the last quarter of a century. The attention of the medical world was first attracted to this form of treatment by Kocher who demonstrated that removal of a part of the thyroid gland was a feasible procedure. Many years prior to this Barry, Graves, and Basedow had accurately described the symptomatology of hyperthyroidism and suggested means for its treatment, but it remained for Moebius to place upon a rational foundation the present day method of treatment by showing conclusively that hyperthyroidism "is the result of the absorption of an excessive amount of substance secreted by a diseased gland" and to him clearly belongs the credit of demonstrating that the disease is "a form of poisoning of the body through an excessive activity of the thyroid" and not a disease of the nervous system or of the vascular apparatus. The correctness of this theory of Moebius is proven afresh with each patient

*Read before the Chattahoochee Valley Medical and Surgical Association, Session 1914, at West Point, Ga.

cured by treatment directed to the thyroid itself.

The incidence of hyperthyroidism is probably greatly in excess of what the average practitioner thinks. Failure to realize this is undoubtedly the cause of its being overlooked in some less fully developed cases. A more important source of error, however, is that many men consider the presence of exophthalmus and goiter as essential symptoms to its diagnosis. Such really is not the case and their presence usually marks a rather advanced stage of the disease. The diagnosis of frank cases of hyperthyroidism is not difficult. Goiter, exophthalmus and tachycardia admit of no other explanation. However, such cases are in the minority and we are much more often called upon to make the diagnosis prior to the development of this pathognomonic symptom complex. It is the consideration of the diagnosis at this early stage that we shall undertake.

It is becoming more and more probable that a diagnosis of hyperthyroidism must be made in all cases in which there is present a long continued tachycardia not explained upon some other pathological basis, and this even in the absence of both exophthalmos and goiter. While tachycardia is thus of very great importance in the diagnosis of hyperthyroidism, other conditions that may induce a tachycardia should be borne in mind. Severe anemia, exhaustion, or long continued nervous strain from any cause may induce a temporary tachycardia. Indeed it is probable that severe and long continued nervous strain, for some unexplained reason, is of importance as an etiological factor in the development of hyperthyroidism itself. Despite these additional possibilities, however, tachycardia, regularly present, remains the most important single symptom of hyperthyroidism. Ranging usually between 120 and 180 impulses to the minute, it may assume at intervals the proportions of a painful palpitation when it becomes an exceedingly distressing accompaniment of the disease. The majority of patients in the early stages present themselves for diagnosis prior to the development of exophthalmos or goiter and frequently complain of but one or two symptoms. Bearing in mind that tachycardia is invariably present these symptoms are usually about as follows:

1. *Muscular tremor.*—Muscular tremor, the most important of the so-called minor symptoms, is elicited by having the patient extend an arm. The number of contractions of the tremor is noted to be eight or nine to the second and very closely resembles the tremor of chronic alcoholism from which upon occasion it becomes necessary to differentiate it. While there is much uniformity in the frequency of the contractions in hyperthyroidism, there is great difference in their degree. The tremor is usually confined to the extremities, more rarely to the eyes alone, and very rarely to one extremity alone. It differs from the tremor of paralysis agitans in that there is no special movement of the part, but rather a fine wave-like contraction of individual muscle fibers.

2. *Muscular weakness.*—Hyperthyroidism always gives muscular weakness as one of its symptoms, both in the early and late stages, but the form to which we have reference here is that occurring in the very earliest stages. A very large number of these patients presenting this intolerable and increasing muscle weakness, seemingly without evident pathological basis, are classed as neurasthenics and their muscle weakness is attributed to nervous exhaustion. The diagnosis of certain of these unusually obscure conditions is much facilitated by bearing in mind the associated symptoms of hyperthyroidism. It is probable that this condition of muscle weakness affecting the muscles of the orbit has much to do with the production of the exophthalmos and the von Graefe and Stelwag signs so common in the more advanced stages of the disease.

3. *Nervous erethism.*—This is one of the most common and one of the earliest symptoms of hyperthyroidism. In some form it is almost invariably present and in certain instances is present to such a degree as to cause serious confusion with hysteria. On the other hand, in contrast to nervous erethism some patients present an exactly opposite condition of nervous depression, with complete loss of nervous control of certain set muscle groups resulting in a form of temporary paralysis. An important member of this group, usually seen however only in the more advanced stages of hyperthyroidism, is paralysis of the external ocular muscles with an inability to move the eyeball and a resulting fixed staring expression.

Affecting the lower limbs there is occasionally seen a group of paralytic symptoms, assuming in some instances the proportions of a paraplegia. The presence of these paralytic symptoms arouses the suspicion of hysteria in the first instance or of a lesion of the cord, myelitic in nature in the second. The perfect sphincter control and the absence of trophic changes should speak against myelitis, and hysteria is ruled out by the absence of hysterical stigmata such as hemianesthesia, narrowing of the visual field, etc.

4. *Loss of weight.*—A gradual loss of weight is in some instances the main cause of complaint even in the early stages of the disease. Loss of weight is always present after the development of the so-called exophthalmic coachexia, but as an early symptom it is of particular importance because loss of weight associated with tachycardia is usually regarded as indicative of tuberculosis. There can be no doubt that many cases of tuberculosis in their early stages do give as their main symptoms loss of weight and tachycardia, often without elevation of temperature or demonstrable physical signs, but usually observation of these patients for a prolonged period of time will show some other evidence of the disease. The important point is that all cases of this character are not tuberculous, but certainly a percentage of them are instances of hyperthyroidism. In the later stages of hyperthyroidism when weakness and loss of weight have become marked symptoms one should not confuse the condition with diabetes. For some unexplained reason sugar is fairly often found in the urine of patients at this time.

5. *Psychical disturbances.*—With certain patients psychical disturbances form an important part of the early history of the disease. There are present particularly in the form of a nervous exaltation, a restless dissatisfied condition or, in common parlance, nervousness. I recall a patient, a young married woman, in whom this nervous exaltation was a most pronounced feature. She seemed consumed with energy, displaying an exaggerated activity, yet after being engaged for but a short time at any occupation she would stop and busy herself with something else. Other than these nervous symptoms, tachycardia and attacks of painful palpitation of the heart, there were no indications of hyper-

thyroidism, yet she recovered completely under treatment for this disease.

Finally, hyperthyroidism is frequently accompanied by certain paroxysmal attacks, the diagnosis of which may be extremely difficult unless the importance of the associated tachycardia and such other symptoms of hyperthyroidism as may be present is appreciated. These attacks consist of nausea, vomiting, diarrhea, and profuse sweating; symptoms by no means peculiar to hyperthyroidism, and the correct diagnosis of which is dependent upon our recognition of their etiology.

Treatment: It is not our purpose at this time to consider the surgical treatment of hyperthyroidism. In any plan of treatment of this disease, however, rest assumes a position of first importance and should be mental and emotional as well as physical. Hygiene and diet are attended to with that degree of thought to which all patients are entitled. Of internal forms of medication, that of Forchheimer is by far the most valuable and its originator reported 82 per cent. of cures. With this method of treatment alone I have not been able to obtain such results, but in combination with the use of the Roentgen ray this treatment offers the most valuable means at our disposal for the control of hyperthyroidism.

A consideration of the pathology of the disease and of the physiological action of the *x*-rays would seem to indicate that as a means of combating a certain definite pathological entity no more appropriate means could be found. Hyperthyroidism is primarily, first and last, a disease of the thyroid gland. The changes are those of an organ in active evolution, the seat of an increased proliferation of glandular tissue, the production of newly formed tubular spaces and a markedly increased circulatory activity. The physiological effect of the *x*-ray is inhibition. They slow up the activity of all glandular tissues, constrict capillaries and arterioles, and decrease function in all organs exposed to their influence. In theory there is no agent more suitable for correcting a definite pathological condition. In practice it will be found that the *x*-rays fulfill in a very exact manner the indications in this disease.

PERIODICITY OF THE DRINK NEUROSES.

By T. D. CROTHERS, M. D.,

HARTFORD, CONN.

Recently there have appeared in the daily papers detailed histories of two quite prominent examples of periodicity and convulsive concentration of nerve energies that has greatly puzzled neurologists, because there is no explanation.

The recorded cases are few, and the theories are vague and uncertain. In this study a grouping of some clinical facts will bring much light to conditions that have otherwise been very confusing. The alternations of exhilaration and depression in the activities of the brain and nervous system are considered mere ebbs and flows of nerve energies of little or no physiological interest.

When these alternations appear in diseases and degenerations of the brain and nervous system they come into prominence as distinct forces, following uniform laws of cause and effect. The neuralgic migraines, the epilepsies, some of the insanities, and a great variety of nerve and functional activities are familiar illustrations.

The drink neurotic who abstains for distinct periods and then suddenly breaks out with insane cravings for spirits, which after a time die away, only to be followed by another outbreak of a similar character, is an example of these unknown cyclic degenerations.

At one time it is a delirium, intense, overpowering, and irresistible and then a period of quiet rest, sanity, and complete control comes on. At one time it is the rigid moralist, strict abstainer, and sound, strong man. At another it is the excessive drinker, immoral, dishonest, without character, and reckless of his acts and conduct.

To the unreasoning public and the foolish theorist this is simply vice—an outbreak of the animal instincts and the beast part of the man. The most delusive and stupid theories have become a great literature in explanations of these two widely differing conditions. The statement that it is simply a gathering and breaking of morbid energies and activities of the brain and nervous functions, governed by distinct physical laws, is not recognized to any great extent.

Some facts common to these conditions will show how thoroughly they are physical and subject to laws which are to be studied. In all probability fully 60 per cent. of all inebriates and alcoholics display this periodicity of symptoms.

In the distinct periodical drinker the free intervals are very often definite as to time, varying from one week to several years, and in many cases breaking out at intervals that are as fixed and unvarying as the movement of the stars. In others this interval of freedom from the drink craze is variable, and in some cases depends on certain conditions which may be often forecasted, controlled, and prevented. In others the conditions are unknown, and the laws that govern their culmination and explosion have not been studied. There is a small class of persons in whom the drink impulse appears as mysteriously as the flash of lightning in a cloudless sky, with no premonition or hint of the coming attack. Often it disappears in the same mysterious way.

An attempt at classification indicates several groups which seem to have fairly constant symptoms. Thus in many cases they may be called the insane impulsive periodic inebriates. The free interval is an unknown condition, and the return of the drink craze is abrupt and unexpected. The man will drink and become crazed at the most inopportune time, on the eve of marriage or some great social, political, or literary triumph, or some business success, or on a public occasion, or at a funeral, where his condition is most disastrous for his future.

A very poor young man with a large family, who had been sober for some weeks was informed that his uncle had left him an immense sum of money, contingent on his remaining sober for one year. Immediately on hearing the news he drank to great excess for weeks.

The reaction when this obsession disappears and the sudden realization of the losses may precipitate suicide. The remorse is so intense that death is preferred. Others, when the drink craze passes off, show the most intense anxiety to explain and minimize the losses which they have suffered from, and also make earnest efforts to convince their friends that this will never occur again.

The memory is usually vague, and events of the past are uncertain and cloudy. In others the memory is clear and intact. The reason and judgment seem to have been suddenly arrested, and

on recovery display unusual activity to promote total abstinence in the subject and his friends. The extreme delirious excitement to help others and to show the dangers from alcohol, and promote the cause of total abstinence, so prominent in revival meetings, is not infrequently the after effect of previous alcoholic excesses. Sometimes this is manifested in egotism and childish appeals to credulity, away beyond the bounds of rational judgment and sense.

Another class of these periodics exhibit distinct premonitory symptoms of the drink craze. Curiously enough, they are unconscious of these premonitions. The more common of these symptoms are degrees of unusual excitement or depression, great business energy or unusual apathy, perhaps exaltation of the emotions or depressive states, with fears of poverty and sudden death. There is a great variety of these symptoms which take on almost every form of abnormality, all leading up to the toxic use of spirits, usually to stupor, and this period is marked by amnesias and delusions that are peculiar to the person.

Sometimes these premonitory symptoms are apparent in hallucinations of sight and hearing or sensory delusions in different parts of the body. At other times there are deliriums of intrigue and low cunning and egotistic duplicities and prevarications, foreign to the patient's previous character.

After spirits have been used up to a certain point all these disappear, generally after the first intoxication. Another class of periodics will have premonitory symptoms of childish reasoning and credulities of the presence of some disease, which will eventually suggest spirits as a remedy. They are often very strong persons, in apparent good health, and seem oblivious to any past experience. Then suddenly they will have food and health delusions, with fears sending them to the physician, who will fail to find anything to sustain their own conceptions of the case.

An example was that of a very prominent lawyer who counselled with many physicians, complaining of most obscure and complex symptoms. Then suddenly he drank to great excess, and after a few days recovered without any recollection of his previous alarm.

Another example was that of a noted banker, who once or twice a year exhibited extraordinary suspicion of persons with whom he was associated, and displayed unusual energy in trying to verify accounts and determine the exact amount in the vaults, examining books and vouchers with the idea of detecting some faults,

These premonitory symptoms are exceedingly varied, and in some degree appear in every instance. The exact recurrence of the drink craze, irrespective of other conditions and surroundings, is evident in many persons. The time in months, days, and hours can be traced, and the occurrence of the drink paroxysm is exact and literal.

It is a question whether the persons always understand that at such an interval they must drink spirits to excess. When they do there is evidently a preparation for this event, and a degree of expectancy which makes it more exact and positive. A number of cases have been noted where this period was a certain number of days and hours, rarely varying, and then never more than a day, and returning under the most extraordinary circumstances.

Examples like the following are not infrequent. A man in previous good health, conducting business in the usual way, will suddenly stop, disappear, and in a short time be found very much intoxicated. Professional men in the midst of most important duties will abruptly give the most frivolous excuses for a change in the work, and become stupid from drink in a short time.

In some instances persons show unusual anxiety to help others or take up some reform work with great energy, ending in a drink attack. Probably this is done in an effort to break up the imperative conception of the oncoming drink craze. The memory during this premonitory period, and even up to the close of the paroxysm is subject to wide variations. In some instances it is entirely a blank, and no efforts to explain the reasons and the causes are made. In others there is a half consciousness of the condition, which is never clear and connected. Very interesting questions have centered about the consciousness and capacity to realize this condition, but are still unsettled. The heredity of these cases is always very prominent.

Probably over 60 per cent. have a neurotic heredity in which insanity, epilepsy, inebriety, idiocy and various other diseases are traceable in the parents and grandparents, pointing to an unstable neurotic condition that is favorable to the outbreak of this distinct form of neurosis. Why it should take on the form of a craze for the narcotism of alcohol is not clear. In all probability this may be dependent on the errors of environment, nutrition, and faulty mental training. Many of the persons studied showed degenerations, perversions, both acquired and inherited. Others indicate a spasmodic tendency to gather and break like a storm, resembling epilepsy, and often merging into it.

These periodicities seldom appear until after twenty years of age, and often subside or merge into some serious degeneration before fifty. At first the length of the paroxysm is brief, confined to a few hours. Later it increases, extending over two or three weeks, then finally becoming shorter and less intense.

The narcotism of spirits develops some other symptoms or conditions which obscure and change the former. There may be intense loathing and repugnance for the odor and effects of spirits, and other drugs are taken. A period of a few years of periodic drinking often merges into morphinism or the use of some other drug.

The periodic drinking, based on a neurotic heredity, frequently merges into epilepsy, paresis, and forms of insanity, marked by exaltation and depression. The drink craze not infrequently dies away, but obsessions remain, sometimes concentrating on widely differing objects. Thus a periodic drinker developed a craze for building houses, which extended over many years, each year building a new house for himself, with different designs and rooms.

Another man developed a craze for travel. Every few months he would stop business and go away, pursuing an aimless journey. Another man has a craze for dressing, another one goes into politics, another becomes a reformer, and so on through an almost infinite list of activity.

The original periodic desire for spirits remains, only it takes on a different form. Oftentimes these cycles appear in epidemic delusions, literally most credulous faiths in unreal theories; faith in commercial and social enterprises, credulous expectations of impossibilities; or, on the other hand, waves

of pessimism, doubt, and confusional conceptions of things.

A number of persons have been noted who began in early life to drink at intervals, and a few years afterwards gave up spirits, and developed into paranoiacs, defectives, eccentrics, and men very sharply unbalanced at times. In political circles, these periodic drinkers who are reformed appear very prominent.

The impulsiveness of conduct, sentiment, and reason, so prominent in many persons, are all phases of these mysterious cycles of brain activity. Spirits, either as a medicine or as a beverage are exceedingly dangerous for such persons. It is often a question of great doubt whether any narcotics should be used. They are all very susceptible to the alternations of drug effects. It is evident that a great many drug and spirit takers have been developed from this class of spasmodic neurotics by thoughtless medication. Masked epilepsies, both in men and women, are of the same class and all indicate great instability and positive degenerations of certain brain centers, and are all suspicious of the possibilites of grave neuroses of some kind.

The alcoholic who has used spirits to the point of poisoning and has all the marked symptoms of congestion, toxemia, and general perversions, is amenable to treatment, with every prospect of restoration and cure. If with this alcoholism there is an hereditary influence and neurosis, the use of spirits may be a symptom at first as well as a cause. If the use of spirits began with distinct free intervals there is still further degeneration and still greater complexity in the prognosis as well as treatment.

The periodical return of the drink paroxysm should be treated successfully, and can be broken up by a great variety of methods and means. The fact that one at intervals is possessed with the desire for drink is a very serious one, and should not be treated lightly. The fact that one is able to stop after the period is over is no evidence of strength, but is decidelly suspicious of a very grave spasmodic disease that will terminate fatally. The fact that periodical drinking has preceded a case of pneumonia is of very grave prognostic importance. The mortality is increased, and any form of treatment becomes impotent. The fact of spasmodic diseases in infancy predisposes to alcoholic periodicity, epilepsy, and other neuroses that must be recognized in after treatment. The gravity of the epileptic paroxysms depends on their duration and persistency. The same thing occurs in the alcoholic paroxysm, only that there are conditions which may be broken up, and thus lessen or check the paroxysm. Persons afflicted in this way come under my care at intervals, with the distinct purpose of checking and breaking up the paroxysm which is expected to occur at about a certain time. This is done in institutional treatment. The hope is that the paroxysm will not return again until the cycle is completed, and this occurs in most instances after short intervals of treatment extending over years.

Such persons should be taught the gravity of their condition and encouraged to seek help from the physician on the first approach of the paroxysm, and in this way break up its return, then become built up and restored so as to overcome the next onset.

Here is a field for practical physicians of the utmost importance, with possibilities of restoration beyond any present conception.

THE HEALTH OFFICER AND THE TUBERCULOSIS PROBLEM IN RURAL COMMUNITIES.*

By S. ADOLPHUS KNOPF, M.D.,

NEW YORK.

PROFESSOR OF MEDICINE, DEPARTMENT OF PHTHISIOTHERAPY, AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

WHEN your Commissioner, the Hon. Hermann M. Biggs, M. D., invited me to address this annual conference of the Health Officers of the State of New York on the problem of tuberculosis in rural communities, I was at first surprised and for the moment could not think that there should be any great difference between the tuberculosis problem in the city and in the town or village. But, after some reflection, I can well see that there is indeed quite a difference in the method by which tuberculosis must be attacked in a community which on the one hand has not the administrative machinery of a large city, and where on the other because of the personal close relations, friendly and neighborly in many instances, the health officer seemingly has not always a free hand to say and do what he thinks is best for the interest of the community at large.

Take, for example, the spitting nuisance. Many a worthy inhabitant of a small village or town should he be forbidden to expectorate freely where he pleases, when in winter he and his neighbors congregate around the warm stove in the grocery store or postoffice and solve the problems of the Universe, would consider an anti-spitting regulation an infringement of his inalienable rights as a free American citizen. The same would probably hold good if, when sitting in summer in front of his own home, he should dispose of his accumulated pulmonary or bronchial secretions or the juices of his chewing tobacco on the sidewalk. It is difficult for this worthy citizen to see how by such uncleanly and unsanitary habit he may not only injure himself and his family, but the entire community.

When, in addition to this, as it happens not infrequently, the careless spitter is upheld by some worthy but retrogressive member of our profession, be it because of political or family antagonism to the present incumbent of the health office, then there surely will be discord and continued spitting. Of course, there are exceptions, but I know that situations such as I have just described do occur, and they make the carrying out of sanitary regulations exceedingly difficult in rural communities.

Tuberculosis, according to Chapter 2 of the Sanitary Code, belongs to the communicable diseases which must be reported to the Health Officer. I can readily see how in a small community there may occasionally arise unpleasant feelings when the health officer insists upon reporting such cases. The fear that after being reported a stigma will be fastened upon an individual or family is often an inducement to hide the disease. We all know the danger of the tuberculous individual to a community, small or large, when he behaves as if he were not tuberculous. Even if he should be careful at home because of the advice of a conscientious family physician, he will often be careless when away from home, disseminating his seven billion bacilli per day by the deposit of his sputum where it will have a chance to dry and pulverize and be inhaled as bacilliferous dust by others. He may

*Address delivered by invitation before the 14th Annual Conference of the Sanitary Officers of the State of New York, Saratoga Springs, N. Y., September 16, 1914.

also propagate his disease through droplet infection. It is very strange how this latter source of infection is sometimes overlooked by otherwise well trained physicians. The expression "dry cough" is even used by some medical men, yet you all know that small particles of saliva are expelled during the cough, even if the individual does not expectorate.

You are all familiar with the laws of June 15, 1913, and the amendment to the county law in relation to tuberculosis hospitals of April 14, 1914. Whenever a county hospital for the care of tuberculous patients is about to be established, I know from experience what a prejudice is aroused among the people against placing such an institution in the vicinity of any community, and there is also the prejudice of many tuberculous individuals against entering such an institution. To be brief, we may put it this way: The most difficult phase of the tuberculosis problem in rural communities is phthisiophobia—the exaggerated fear of the presence of a tuberculous individual. On this fear is based the disinclination of prospective patients to have their chests examined during the onset of early symptoms, such as cough, loss of weight, rise of temperature, hoarseness, sanguineous expectoration, etc. They and their relatives fear being stigmatized in the event tuberculosis is diagnosed and reported. Phthisiophobia is responsible for the disinclination to obey anti-spitting laws, the disinclination of the community at large to have tuberculosis hospitals or sanatoria in the neighborhood, and last but not least, the disinclination of individuals to enter these institutions for treatment and cure.

To some of you younger men with less experience it might sound strange when I tell you that the majority of tuberculous individuals think themselves perfectly harmless and are afraid to enter tuberculosis institutions for fear of becoming infected there; and this fear is not infrequently shared by other members of the family. We all know that the successful treatment in the home of the patient, while feasible in some instances, is impossible in many. And yet, upon the early discovery and the prompt treatment of the tuberculous invalid at the right time and in the right place depends in no small degree the solution of the tuberculosis problem.

What can the health officer of a rural community do in the face of these tremendous difficulties which confront him in his honest and sincere effort to be helpful in the combat of tuberculosis?

Will you permit me to answer this question by picturing to you my ideal of the health officer of a rural community, and then in the lively discussion which I hope will follow my humble contribution I beg you to show me wherein my conception falls short? We will then have before us a worthy ideal for you to follow.

First of all, the model health officer of a rural community must be an ideal man; he must be beloved for his personality, and for his tact in dealing with patients, with his fellow physicians, and the other authorities in the community. He must be a thoroughly trained sanitarian. While it would be desirable for him to have a degree of Doctor of Public Health besides the degree of Doctor of Medicine, this to my mind is not absolutely essential, but he must be a thoroughly trained medical man to whom his fellow practitioners can look up and on whom they can call for counsel.

In last week's issue (No. 36, Vol. 29)* of the Public Health Reports, published by the U. S. Public Health Service, in an article entitled "The Making of Health Officers," my good friend, Assistant Surgeon-General John W. Trask, in deploring the fact that "there are exceedingly few men with requisite training from among whom the thousands of local health officers can be appointed," recommends a correspondence course in health administration and allied subjects for improving the efficiency of these officers. I most highly approve of this suggestion, but would urge that facilities for clinical instructions should be provided in addition, for the ideal health officer should not only be versed in sanitary science in general and be familiar with all the means of preventing endemic and epidemic diseases, but he should also be an expert diagnostician of communicable and contagious diseases, which knowledge cannot be acquired by correspondence.

Besides being all this, he must have not necessarily the gift of oratory, but the ability to give good practical talks to physicians and to laymen on medical topics, sanitation, and the prevention of disease. Last but not least, and I say this with all due respect for the authorities, the health officer of any county must and should be paid a salary high enough to make him independent of practice, so as to enable him to devote all his time to his official duties. The position should be for life, as long as he is able to do his duty. It should never depend upon political preferment.

If the community is too small to maintain a well-paid health officer, let us follow the suggestion of Mr. Geo. J. Nelbach, of the Tuberculosis Committee of the State Charities Aid Association, and unite a number of the smaller communities under the administration of one health officer, who, because of being well paid, can be held responsible for the sanitary conditions of the various communities comprising his sanitary district or unit.

And now, what are his particular duties concerning the tuberculosis problem? After having united with his fellow practitioners of the community to form an anti-tuberculosis league, after they have pledged themselves to aid him in a conscientious war not against the tuberculous but against tuberculosis, he should give regular popular talks to the town or village folks on the prevention of this disease, of course always under the auspices of the local physicians. The conscientious health officer should prepare himself carefully for such tuberculosis conferences. Pray, do not think that it is so very easy to talk the language of science in the language of the people. Nothing is more difficult than to avoid scientific terms when accustomed to them, and at the same time nothing is more detrimental to the good effect of a popular medical talk than the use of big words and phrases familiar to the medical ear, but sounding like Greek, Latin, or Hebrew to the lay mind.

Let the lecturer begin by defining tuberculosis, not as a dangerous contagious disease, but merely as a communicable one, which only becomes dangerous through ignorance and carelessness. I ascribe the wonderful success of the antituberculosis work in New York City, inaugurated by your distinguished commissioner and my distinguished teacher, Hermann M. Biggs, to the fact that from

*"The Possibility of State Departments of Health Improving the Efficiency of Local Health Officers by Means of Correspondence Courses."

the very onset of his propaganda he classified tuberculosis with the communicable and not with the contagious diseases. One must first overcome the fear of the disease in order to combat it successfully. It is a good thing to tell a lay audience that probably every one of them, or at least nine-tenths of them, have or have had tuberculosis at one time or another in their lives, and that we are not at all certain that a slight attack of tuberculosis does not confer upon us a certain immunity to future attacks. Explain, furthermore, that when we are in good health, thanks to the bactericidal quality of the Schneiderian membrane in our nose, the upward waving sciliæ in the upper respiratory tract, the phagocytic power of the antibodies in our blood, and the bacteria-killing power of the gastric secretions, we have natural factors of defense against tuberculosis. Otherwise, probably everyone of us would be ill with the disease. Then emphasize in as strong language as you can possibly put it in that the honest conscientious consumptive, who takes care to avoid infecting others by his sputum or saliva, is not a danger to his fellow men and is as safe to associate with as anybody else.

To explain to a lay audience the difference between a contagious and a communicable disease, take smallpox as an example. Tell them that no matter how clean and conscientious a smallpox patient may be, they should not go near him nor touch him, unless they have been vaccinated and revaccinated, and they should stay away from the smallpox hospital in general. On the other hand, say to your audience, "You may safely touch and shake hands with the conscientious consumptive and even kiss him on the forehead, if you must kiss, and nothing will happen to you," and then tell them that the well-equipped and well-conducted tuberculosis hospital or sanatorium is the safest place not to catch consumption.

Never fail in your popular tuberculosis talks to lay emphasis on the value of early diagnosis and impress upon your hearers the fact that an annual or semi-annual examination of their chests by their family physician is one of the safest and from every point of view most profitable investment for retaining or gaining health they could possibly make. Since you counsel these people to be examined by their own physicians they will see the altruism in your giving this valuable advice.

In reference to the tuberculosis institution, hospital, or sanatorium, you can also conscientiously say that no physician, no nurse, no visitor, or healthy inmate ever contracted tuberculosis there, because of the careful training of the patients and the splendid hygiene in vogue in such institutions. This also should be told to those who object on sentimental or sanitary grounds to the establishment of tuberculosis institutions in their neighborhood. The mortality from tuberculosis among the inhabitants of villages surrounding sanatoria invariably decreases after the establishment of such institutions. To those who object on account of depreciation of real estate value, prove to them by existing statistics, which are available to all, that real estate has improved in the vicinity of institutions for the tuberculous and you will very quickly win over to your side the real estate owner and the real estate dealer.

In your talk to villagers and farmers, and particularly to the women, teach the value of fresh air, of which they have so much in the country, and of which they make so little use; tell them that the fear of night air is a nightmare, for it is just as good as day air. Teach the children and the adults the art of deep breathing; teach your audience all about proper food, regular habits and the danger of intemperance, since alcoholism is a strong predisposing factor to tuberculosis. Insist upon the enforcement of anti-spitting laws; have your people do away with the roller towel at home, in hotels, or other public or private wash-rooms. In my travels through the State I have found a goodly number of hotels in which the roller towel and the common drinking cup seem to be still permanent fixtures, and badly kept spittoons the usual ornament of the lobbies and public assembly rooms. Encourage outdoor sleeping, which can be carried out so much more easily in smaller communities than in larger ones. Stop the chiming of bells and the striking of the town clock between the hours of 9 P. M. and 7 A. M., and stop other unnecessary and distressing street noises; they are as bad for the nerves of the indoor as the outdoor sleeper, and it is as bad for the tuberculous as for the non-tuberculous to be kept awake at night. Except in small villages, I don't see any earthly reason why the rooster nuisance could not also be done away with as has been done in New York City, where we recently passed a regulation, which will go into effect on November 1. This regulation will not permit residents of the Greater City of New York to keep roosters; it will also prohibit persons from raising chickens in their back yards where there is another residence or public institution within 75 feet of the poultry enclosure.

Improve the hygiene of your rural schools. In our large cities we erect the most beautiful buildings for our school children; in some villages and small towns anything from an old barn to the old-fashioned red brick building with low ceiling, with little or no ventilation, and bad lighting, has to do. Remodel these schools into open air schools, or build new ones in which you will have plenty of open air classes. I have said before, and am willing to say again, that in my humble opinion open air schools at least for primary grades must become the rule and indoor classes the exception if we wish to prevent and combat tuberculosis in childhood.

You should even concern yourselves with the hygiene of the churches. They should be properly ventilated and frequently cleaned. In Protestant churches advocate the use of individual communion cups and in Catholic churches see to it that crosses, and other articles of adoration, often kissed by the devout, are frequently disinfected.

Give anti-tuberculosis talks to ministers and teachers or directly to the children; distribute popular medical literature in schools for the children to take home; make fresh air apostles of these little ones and you will reach the old folks at home and thus combat the tendency to tuberculosis in the adults and the young; enforce your laws against bovine tuberculosis, for bear in mind that 10 per cent. of the tuberculosis in childhood is due to the bovine type of the disease. Allow no individual with an open tuberculosis to be employed in a dairy or in the handling of milk in stores.

You will, of course, see to it that all suspected sputum sent to you is carefully examined, but tell your physicians that often several specimens are necessary in order to find the tuberculosis germ, and last but not least, repeat to them as often as you can the maxim that while the presence of tubercle bacilli in the pulmonary secretion of the in-

dividual is absolute proof of the existence of the disease the absence of the germ does by no means prove that there is no tuberculosis. In the earlier stages of the pulmonary type of this disease the germs are found but rarely because there is little disintegration of pulmonary tissue, and yet it is in this early stage that we can most hope for complete recovery. It is, therefore, of vast importance that every community should have physicians who are experts in the physical diagnosis of the disease in its earliest stages, and the health officer of a community should be particularly qualified to aid his fellow physicians in the early discovery of tuberculosis.

See to it that every case of open tuberculosis receives hospital or sanatorium care or at least gets his sanatorium treatment under intelligent guidance at home. There should be no uncared for tuberculous individual in any community which has an efficient health officer and an intelligent municipal or county government. Make your sanatorium a center of education for physicians and laymen; make your hospitals for advanced cases attractive so that those who ought to enter will enter willingly and will be glad to be there because they will receive better treatment than they could at home; if the institution has cheerful and attractive features they will miss the home less.

The consumptive is the ideal victim of the quack, charlatan, and vendor of patent medicines, and this is particularly true of the consumptives who live in rural communities where often the local papers derive their greatest income from advertising nostrums and sure cures for consumption and other diseases. Have a health publicity column in your local paper to enlighten the public. If necessary, have the department pay for this to compensate the poor editor for his loss of quack advertisements. Tell your lay audience that there is no sure cure for consumption; that good air, rest, and good food under careful medical supervision, and the scientific administration of medicine to relieve distressing symptoms are up to this date our only means of curing tuberculosis, and that every advertisement of a sure consumption cure cloaks a swindle.

In all your talks to laymen try to imbue them with your own enthusiasm and devotion to the anti-tuberculosis cause. Tell your hearers that tuberculosis is not merely a medical disease but that it has a very large social aspect. Bad housing, overcrowding, dangerous congestion, and even underfeeding exist, alas, not only in our large cities but also in smaller communities. Show your wealthy and influential fellow citizens what great good they can accomplish by becoming interested in the amelioration of such conditions, as are conducive to the spread of tuberculosis. They will themselves benefit in the end from a clean and healthful community. Personal service to the consumptive poor and kind, generous, and considerate actions toward those afflicted with tuberculosis, rich and poor alike, will create a better and more helpful feeling throughout the community.

It is essential, in order to prevent and cure the disease, that the laymen and physicians of the community, whether large or small, should forget their little social, political, or religious differences and work hand in hand for the common good. Then and then only can you hope to come near the solution of the tuberculosis problem in your midst.

16 West Ninety-fifth Street.

Medicolegal Notes.

Revocation of License—Offering to Procure Abortion—Construction of Statute.—The Missouri statute, Rev. St. 1909, §8317, authorizes the State Board of Health to refuse a license to practise medicine and surgery to persons guilty of unprofessional or dishonorable conduct and to revoke licenses for like causes, and specifies certain acts which shall be deemed unprofessional and dishonorable conduct, namely, habitual drunkenness, drug habit, excessive use of narcotics, producing criminal abortions, or soliciting patronage by agents. It was, however, provided that these specifications were not intended to exclude all other "acts" for which licenses might be revoked. A physician was suspended by the Board of Health for one year upon a charge of unprofessional and dishonorable conduct in offering or being willing to commit a criminal abortion. It was held, in a suit to quash the action of the board, that an advertisement by a physician, stating that his practice was limited to "diseases of women and surgery," and the testimony of a witness that several physicians had told him that such physician had the reputation of being a criminal abortionist, would not sustain a suspension from practice.

The right of a licensed physician to practice is not a mere shadowy privilege which may be revoked regardless of whether the possessor has violated the laws of the state, but is a valuable privilege and perhaps a property right, which is protected at least by such safeguards as the legislature has thrown around it. The statute on which the suspension was based is, so far as it authorizes the revocation of licenses, highly penal and must be so construed, that is, with a degree of strictures commensurate with the severity of the penalty it imposes. Where the penalty is onerous, no one can be held to have violated its provisions unless his acts come within both the letter and the spirit of the law. Under the statute, it was held that a mere willingness or offer to produce an abortion would not justify suspension from practice. The general specification in the statute could not be applied to mere evil thoughts or a consent to do wrong where no wrong was actually done. It could not logically be urged that a mere desire or willingness to use intoxicants or narcotics excessively would impair the mind; and for the same reason it must be held that a mere consent to perform an abortion would not make the physician an abortionist, or subject him to the penalties of having committed that crime. The general specification of the statute was directed solely against certain undesignated acts, not against evil thoughts or a willingness to perform wrongful acts. There being no law or rule prohibiting offers to commit abortion, the board could not suspend a physician for offering to commit an abortion.—State v. Robinson, Missouri Supreme Court, 161 S. W., 1169.

Liability of Department Store for Medical Services Rendered to Employee.—In an action by a physician against a department store for services rendered to an employee under contract with the superintendent, the evidence conflicting as to whether the superintendent had authority to bind the company by the contract, it was held that the question was one for the jury. If the contract made by the superintendent was unauthorized, the question whether it was subsequently ratified by the president of the corporation operating the store was also for the jury. There was no doubt that the corporation itself had power to employ a physician to treat a patient while in its employ, and the president of the corporation possessed the implied authority as incident to that office to execute such power. Although the fact that a person merely calls a physician to attend a third party does not raise an implied contract upon such person's part to pay therefor, unless he was under legal obligation to furnish such services, yet he is liable if there was in fact an actual contract to pay, and an express promise to pay is not essential, if it sufficiently appears from the facts and circumstances that the physician intended to charge for his services, and the person requesting him to perform them intended to pay therefor. So in this case, though it might be that no one in express words promised to pay the plaintiff for his services, he might nevertheless recover on contract if the jury found as a fact that he rendered the services at the request of the defendant corporation with an intention on his part to charge, and that the defendant intended to pay therefor. Whether there was such an actual contract to pay for the services was a question for the jury.—Ghio v. Schaper Bros. Mercantile Co. (Mo.), 163 S. W. 551.

HYPERSENSITIVENESS, FEVER, AND METABOLISM.

THE conception of anaphylaxis has opened up many new vistas of research in clinical medicine. Particularly in the domain of the infectious diseases has it served to explain at least in part such phenomena as fever, and changes in metabolism and in the blood. At the same time anaphylaxis itself has been delineated as merely one of the manifestations of parenteral digestion. Erich Leschke in the *Beiträge zur Klinik der Infektionskrankheiten und zur Immunitätsforschung*, Vol. 3, Nos. 1 and 2, defines anaphylaxis as follows: Upon the parenteral introduction into the body of a foreign protein, antibodies of the nature of protective ferments are formed and with the aid of complement serve to disintegrate or, in other words, to transform this protein. The toxic products resulting from the further parenteral introduction of the foreign protein cause the symptoms of anaphylactic poisoning. It is pointed out that F. Kraus was the first to perceive the close relationship between the fever resulting from infection and the reactions of immunity. The conception of anaphylaxis gave a new meaning to this febrile reaction. In 1895 Krehl established the fact that the parenteral introduction into the normal organism of foreign protein evokes in small doses a rise in temperature, and in large doses a fall in temperature. It was later found by Krehl and Matthes that the fever resulting from protein injections was higher if the animal had already received an injection of the same protein. Leschke subjected this problem to further investigation, using for this purpose guinea-pigs, rabbits, and dogs, and likewise found that in every instance the temperature reactions are dependent upon the amount of foreign protein introduced. He thereby characterizes this varying mode of reaction as one of general biological significance. He found moreover that the same reactions occurred in the production of passive anaphylaxis as in that of active anaphylaxis, in other words, the injection of anaphylatoxin caused the same reactions in the above species of animals as the repeated injection of foreign protein. Whatever differences in the febrile curve may exist among these different species are attributed to the different content in complement of the respective sera. Leschke believes that the anaphylatoxin is not a homogeneous substance but is a mixture of various substances. He conceives of pyrogenous and toxic components of the anaphylatoxin, which components are separate and distinct substances. Indeed, a third component has been differentiated by Dold and Rados and named phlogistin. This elicits an inflammatory reaction and may be isolated from the toxic component by virtue of its filterability through the Berkefeld filter and its greater resistance to heat. The inflammatory reactions are well known clinically in the Arthus phenomenon that occurs locally when a foreign protein is injected into a sensitized animal, and in the local tuberculin and luetin reactions.

The question that next presented itself to Leschke was the identification of the different split products of the parenteral digestion of protein. Biedl and Kraus had pointed out the resemblance of anaphylactic shock to peptone poisoning. Still later these investigators as well as Pfeiffer and Aronson alluded to the identity of these reactions with those produced by synthetic histamin or β-imidazolylethylamine. Leschke investigated the effect of peptone and of histamin upon the temperature. He found that neither in dogs nor in rabbits and guinea-pigs has pure peptone any effect upon the temperature. The fall in temperature observed after the injection of large amounts of peptone is attributed to the effect of other and more remote split products. It was found by von Knaffl-Lenz that the blood-pressure lowering and the blood-coagulation inhibiting effects of peptone are dependent upon the tryptophan present in peptone. Leschke found that histamin causes no change in the temperature. Moreover, not only in their effects upon the latter are histamin, peptone, and anaphylatoxin to be differentiated, but likewise in their effects upon the blood-pressure, the uterus, and the blood cells, and in the production of necrosis. Moreover the above three substances differ markedly in their physicochemical constitution.

In connection with this subject another important question at once arises. Since the anaphylatoxin seems to be non-specific for all bacteria and all types of protein, that is, the same toxic end-product arising from the parenteral digestion of protein, it is legitimate to ask whether in each instance or in each infectious disease there are not other and specific toxic end-products. Of course the diversity of the infectious diseases speaks in favor of the existence of such specific end-products. Recent investigations have revealed the presence of such substances but await confirmation.

The relation of anaphylaxis to metabolism is another subject of eminent interest and importance. A number of investigations have shown that foreign protein introduced parenterally is burned up and utilized exactly as when introduced into the alimentary canal, and tends to maintain the protein equilibrium up to the point of the development of anaphylaxis. At this stage the nitrogen metabolism undergoes a marked change. In the presence of anaphylactic fever, on account of the motor unrest, the vomiting, the tenesmus, etc., the nitrogen-balance becomes negative. If these accompanying symp-

toms are controlled by the use of opiates, the nitrogen-balance then becomes positive. However, in the behavior of the nitrogen metabolism a number of factors must be borne in mind. According to the size of the sensitizing dose, the intervals of administration, the amount of the antibodies produced, the relative individual or race susceptibility, the size of the repeated dose, and the site of its administration, there may result in one case fever or in another case a fall in temperature, or there may occur an enteritis, hemorrhages, choking, tenesmus, motor unrest, convulsions, apathy, respiratory and circulatory disturbances, and local inflammatory reactions. All of the above manifestations influence singly and in different combinations the protein metabolism. At any rate, the primary effect of the anaphylactic poison is to retard the protein as well as the general metabolism. This restriction occurs without regard to the temperature effects both when the temperature is elevated and when it is lowered. In many cases, however, the protein metabolism is increased as the result of the accompanying manifestations of anaphylaxis, as detailed above.

By means of calorimetric studies Segale has recently studied the effect of anaphylactic shock upon the total energy and tissue exchanges of the body. His observations show that in acute anaphylactic shock there is a fall in the body temperature and in metabolism, but the fall in the temperature is much more rapid than the fall in the metabolism. In chronic shock there is in the beginning synchronous with a fall in the temperature an increased production of heat. The question arises whether this is the result of the anaphylactic poisoning, or whether, as Leschke holds more probable, it is the result of associated manifestations of anaphylaxis, such as motor unrest, etc. At any rate the variations in metabolism and in temperature are not parallel. Finally, however, in chronic anaphylactic shock, as in the acute type, there occurs a fall in the heat production corresponding to the fall in the total metabolism.

Of greater clinical importance than the subject of anaphylactic shock is that of anaphylactic fever. Leschke in conjunction with Hirsch investigated the fever resulting from active anaphylaxis and that resulting from poisoning with anaphylatoxin. They found that both types of fever cause a restriction in the total energy and tissue exchanges. The most significant fact standing out from their experiments is that in febrile conditions the metabolism and the temperature do not necessarily follow a parallel course. The hitherto prevailing individualistic conception of fever must therefore give place to a dualistic conception which draws a sharp line of demarcation between the change in metabolism and the rise in temperature. There are types of fever in which the metabolism may be normal or even diminished. In these cases the influence of the endotoxins would appear to be in abeyance while the products resulting from the parenteral digestion of the disintegrated bacteria come into play as the sole disturbing factors. The main fact to be borne in mind is that all the manifestations of infectious fever are not to be attributed to the same uniform cause.

COCCYGODYNIA.

While the average case of coccygodynia is easily diagnosed, there are occasional cases where confusion is apt to arise unless one is particularly careful in the differentiation of this affection from others occurring in this region and giving rise to pain in about the same situation. Sometimes, also, an error is made that would be easily avoided if one were thorough in getting the history and equally thorough in making the examination. It is unfortunately true, however, that errors in diagnosis have occurred with considerable frequency and, appreciating this fact, Hamant and Pigache (*Revue de Chir.*, January, 1914), have made a rather extensive critical study of this condition. Among other things, they call attention to the fact that coccygodynia has often been confused with, or even been called a symptom of, fissure or fistula in ano, inflamed hemorrhoids, prostatitis, metritis, salpingitis, ovaritis, and retroversion of the uterus. Formerly considered a malady peculiar to adult females, in recent years it has been realized that no sex or age is exempt, cases having been reported even in children under 5 years of age.

Marro (Thèse de Paris, 1912) distinguished three sources of coccygodynia: (1) those of obstetrical origin, following a difficult labor with or without forceps; (2) those of genital origin, accompanying disease of the uterus or its adnexa, or, in the case of the male, chronic prostatitis; (3) those of extragenital origin, (*a*) traumatic, caused by blows or falls, (*b*) non-traumatic, in which he included diseases of the anus, rectum, or musculature of the perineum, tumors, constipation, etc. Hamant and Pigache, however, make the point that coccygodynia is not a syndrome, but should be considered a definite clinical entity, always traumatic in origin, having a distinctive pathology and symptomatology, and always relieved by the removal of the coccyx, no matter what other lesions may be present in the genital or anorectal tissues. They find a chain of symptoms which they consider pathognomonic. Most frequently, after a fall or blow upon the coccygeal region a very sharp pain is experienced in that situation. At other times, this pain is produced in women whose accouchement has been particularly difficult. If, during the following days, it diminishes, even to the point of disappearing upon lying down, it reappears with a hopeless tenacity at the least change of position, and upon making the least movement—walking, going up or down stairs, arising from or seating one's self in a chair, defecation, etc. This pain may be dull, lancinating, stabbing, burning, tearing, gnawing. Rarely there are irradiations along a nerve. The pain is seldom continuous, but is ordinarily provoked by the movements and changes of position of the patient. Still, one may find a continuous pain when coccygodynia is complicated by abscess in that region. When lying down or standing erect there may be no pain; but pain is produced by the least movement resulting in pressure or muscular pull upon the coccyx, and these phenomena may persist for years. Upon examination there may be ecchymosis over the sacrococcygeal region; external palpation soon after the injury

reveals tumefaction and marked tenderness on pressure, while rectal touch gives rise to the most excruciating pain, and the coccyx can usually be felt projecting forward, sometimes forming even a right angle with the sacrum. The coccyx is movable, may be pushed back to its normal position by intrarectal manipulation, but usually soon returns to its former malposition.

In summing up, Hamant and Pigache's conclusions are essentially as follows: The word coccygodynia, which even up to these last few years has been used to designate all painful affections, whatever their nature, situated in the sacrococcygeal region, should be reserved hereafter for those pains, provoked or spontaneous, which are localized exclusively at the coccyx. This affection, characterized essentially by the acuteness and the tenacity of the pain, is the consequence of a luxation or fracture of the coccyx, following a traumatism which may be internal (difficult labor) or external (fall or blow upon the coccyx). Its treatment is strictly surgical —the complete resection of the coccyx curing the coccygodynia definitely and without being followed by any functional disturbances.

We have dealt with this subject at some length because it would seem that the stand taken by Hamant and Pigache, that coccygodynia is a distinct clinical entity, and not a mere symptom of something else, is correct. The sooner this is generally realized the better for a host of sufferers from coccygeal injuries who are now being treated for real or fancied gynecological ailments or classed as simple neurasthenics.

SOMATIC SYMPTOMS IN DEMENTIA PRÆCOX.

As is well known attempts have been made to connect dementia præcox with intestinal autointoxication, anomalies of internal secretion and other somatic causal elements. The connection between the psychoses and low physical vitality is said to be very obvious. Many peculiarities of behavior in these subjects require no further explanation than a purely physical insufficiency, one which cannot, moreover, be overcome by the resources at our disposal.

At the summer session of the Naturwissenschaftliche-medizinische Gesellschaft zu Jena, Medical Section (*Muenchener medizinische Wochenschrift*, August 4), Schultz reports new somatic finds in this affection. The first refers to a blood picture. Blood taken from the lobule of the ear shows an increase in erythrocytes, indicating capillary erythrostasis. This is often found throughout the disease, in incipient cases, chronic cases, relapses, and in end stages. The leucocyte formula shows alterations corresponding to the stage and degree of the disease. The red blood cell picture in dementia agrees with that seen in diseases of internal secretion. The author was able to confirm the finds of Abderhalden and others in regard to serodiagnosis of the disease. Finally dementia præcox agrees with organically conditioned psychoses in exhibiting the phenomenon of adrenalin mydriasis in a very large proportion of cases. Functional psychoses and psychoneuroses do not show this symptom.

THE GASTRIC DISTURBANCES OF CARDIAC INSUFFICIENCY.

ONE of the classical distinctions noted in the gastric derangements of heart disease is that in mitral lesions there is a tendency to dyspepsia, whereas in aortic disease painful manifestations predominate. According to G. Faroy and C. Lian in the *Gazette des Hôpitaux*, June 23, 1914, this distinction is not an exact one. Mitral lesions may be accompanied by painful gastric symptoms and aortic lesions may be associated with dyspepsia. A more rational differentiation may be made between the following two groups of cases: In the first the congestion of the stomach as the result of cardiac insufficiency causes an impairment of the functional capacity of the stomach, and this may occur in all types of heart disease. The second group of cases comprises those in which the periaortic abdominal sympathetic plexuses are involved or in which there is perhaps an intermittent claudication of the stomach. These cases are characterized by the painful epigastric crises that are observed in abdominal aortitis. The dyspeptic cases may be subdivided into three categories. In the first, which includes three-fourths of all cases of cardiac insufficiency, the dyspeptic symptoms are either mild or are else masked by the other symptoms of cardiac distress. In the second category the gastric disturbances are so pronounced that they are complained of equally with the other symptoms, such as dyspnea, palpitation, etc. To the third category belong these cases in which the dyspeptic symptoms alone occupy the foreground, and in which the cardiac impairment may be unsuspected or may be revealed only on careful examination. The symptoms of the cardiac dyspepsias include anorexia, epigastric fulness, eructations, vomiting, etc., in other words, the entire gamut of sensorimotor disturbances of the stomach. In the diagnosis of these cases it is essential to exclude the cardiac disturbances secondary to gastric derangements, the cases of coincident gastric and cardiac distress secondary to uremia, the cases of gastric disturbances resulting from the abuse of digitalis or from other medication, and the cases in which gastric and cardiac troubles are a mere coincidence. If the diagnosis is in doubt, the intramuscular injection of a suitable preparation of digitalis may furnish the proper therapeutic test.

THE JAW-WINKING PHENOMENON.

MORE than seventy cases of this condition have been reported. According to E. A. Cockayne in the *British Journal of Children's Diseases*, August, 1914, the phenomenon consists in the involutary raising of the upper lid coincident with some movement of the jaws, face, tongue or pharynx. Frequently the lid movement is accompanied by ptosis on the affected side. The anomaly is usually unilateral. In addition to ptosis there are often other defects, the commonest being paralysis or paresis of the superior rectus muscle. The movements concerned in the above reflex have been analyzed by Sinclair. In some instances with an associated ptosis the upward movement of the lid occurs when the mouth is opened with a lateral movement of the jaw. In other instances with ptosis the lid movement is synchronous with a lateral movement alone of the jaw. There are other cases without ptosis in which the lid and jaw movements are associated.

Pontico found that almost all the movements were allied to those controlled by the motor branch of the fifth, or by the sixth and seventh nerves. The commonest type of the jaw-winking phenomenon is that in which the lid is raised during ordinary mastication. In some cases the lid is raised to such an extent as to show a large area of sclerotic above the cornea, at the same time that the jaw is moved laterally away from the side of the lesion. The condition is to a certain extent familial and hereditary and tends to disappear. The most commonly accepted theory as to the pathology of the condition is that those cells of the third nucleus which supply the motor fibers to the levator palpebræ superioris are defective and that there is a direct innervation from the motor nucleus of the fifth nerve. The author suggests that a more probable cause of the phenomenon is a defect of the whole motor path concerned in the movement of the upper lid or at any rate of the part above the nucleus of the third nerve. The condition is probably the result of a defective or arrested development.

The Question of Lipoid Antibodies.

A subject of fundamental importance in the determination of the nature of the reaction of the body fluids and cells to the invasion of foreign substances is the problem as to whether substances other than proteins are able to evoke specific antibodies. The fact that the lipoids are to-day receiving so much attention from biological chemists is sufficient warrant for the inquiry as to whether these peculiar substances likewise arouse the production of antibodies. The solution of this problem has been sought by Much and Adam (*Beiträge zur Klinik der Infektionskrankheiten und zur Immunitätsforschung*, Vol. III, Nos. 1 and 2). These investigators inoculated rabbits over long periods of time with lipoids obtained from various sources, such as carcinoma, placenta, muscle, and brain, and in no instances were fat antibodies produced. It was found, moreover, that this failure was due to the fact that water-soluble end-products of the tissues extracted inhibited the formation of the lipoid antibodies. There was apparently evidence of an antagonistic action between two partial antigens. A lipoid obtained from egg-albumin by extracting the latter with ether produced by animal inoculation a strong complement-binding reaction toward this lipoid. On the other hand, the residue of the egg-albumin left after the evaporation of the ether produced a complement-binding reaction toward albumin. What the actual inhibiting substance is in relation to the humoral lipoid antibody production has not been determined. Certain experiments, however, seem to indicate that substances residing in the cell nucleus exercise this inhibition.

The Literature of Military and Naval Medicine.

The problems of medicine and surgery arising in the course of warfare have much in common with those of peaceful times, nevertheless they possess certain elements peculiarly their own. The utilization in the present combat of every known device for wholesale destruction and mutilation, not to mention the application of the latest methods of camp sanitation and preventive medicine to the largest aggregations of men that have ever been assembled for war, bids fair to provide food for comment and discussion for many years to come. Military and naval medicine has long ago been raised to a specialty, and has its own bibliography. There is no dearth in the periodical journals devoted exclusively to this subject in different countries, and there will probably be no famine in material for these journals when the present war is over. England has its *Journal of the Royal Army Medical Corps;* France, *Le Caduceé;* Belgium, the *Archives Médicales Belges;* Russia, the *Journal de Médecine Militaire de la Russie;* Germany, the *Deutsche militärärztliche Zeitschrift*, and Austro-Hungary, *Der Militärarzt*. The Italian services are represented by the *Giornale di Medicina Militare* and the *Annali di Medicina Navale e Coloniale;* Spain has its *Revista de Sanidad Militar*, and the United States has the *Army and Navy Journal* and the *Military Surgeon*. Last but not least must be mentioned the *Bulletin International des Sociétés de la Croix-Rouge*, whose motto, "inter arma caritas," is inscribed beneath the emblem of the Red Cross.

Loewi's Pupil Phenomenon

In 1908 O. Loewi described an observation made by him on dogs and cats from which the pancreas had been removed. When adrenalin was instilled into the eye the pupils were dilated. This was at first held to mean that the pancreas exerts a sympathetic inhibition on the dilator of the pupil. Last summer Loewy and Rosenberg repeated the experiments of Loewi and reported the results to the Berlin Physiological Society (*Berliner klinische Wochenschrift*, August 17). It was found that the pupillary phenomenon occurred under any condition in which there was hyperemia. Hence the discovery of Loewi cannot be due to any internal secretory substance in the pancreas.

News of the Week.

Harvey Society Lectures.—The first lecture of the series 1914-15 will be given at the New York Academy of Medicine, 17 West Forty-third street, on Saturday evening, October 10, at 8.30 P. M., by Prof. Frederick P. Gay, of the University of California. Subject: "Experimental Studies on Methods of Anti-Typhoid Immunization."

Ontario Surgeons Barred from the British Army.—A number of Canadian surgeons who have volunteered for service in the British Army have, it is said, been rejected by the War Office on the ground that they are not qualified to register as British practitioners. Ontario, it appears, has refused the British offer of reciprocity in medical licensure on the alleged ground that the British qualifications were not up to the Ontario standard. The only way out of the difficulty is for the Canadian surgeons to obtain British qualification through examination, since Ontario is apparently unwilling to accept reciprocity in registration.

More Red Cross Surgeons Wanted.—So appalling is the number of casualties in the European war that the regular and volunteer surgeons attached to the armies are utterly unable to take care of wounded, many of whom, after days of suffering, die from sheer neglect. There is work, therefore, for an almost unlimited number of independent surgeons serving in the Red Cross, the only thing in the way being a lack of funds for the support and

transportation of the surgeons and for the needed supplies. The Duchess de Talleyrand (formerly Miss Anna Gould) some days ago asked for four American surgeons, offering to supply them with free tickets to France if they would volunteer for Red Cross work. Nurses are also urgently needed. The *Red Cross*, which sailed from New York two weeks ago with ten surgical units to be distributed among the several nations at war, has arrived on the other side, and the surgeons and nurses have been sent to their designated stations.

Enforcing the Dog Muzzling Ordinance.—Active steps to enforce the dog muzzling ordinance recently enacted by the Board of Health of this city, began on September 15. During the week following 1307 dog owners, who neglected to conform to the requirements of the law, were served with copies of the ordinance, and were warned that prompt compliance was necessary. Following such notification, non-complying dog owners were summoned to court, and during the week ending September 22, 59 were fined by various magistrates, while in 20 cases sentence was suspended. During the month of August 5258 stray dogs and 22,459 cats were seized and destroyed by the American Society for the Prevention of Cruelty to Animals.

Disease Prevention Day.—Indiana has instituted what is called a Disease Prevention Day, on which parades are held and speeches made to impress upon the people the necessity as well as the possibility of conserving the health of the community and warding off disease. October 2 was the first of these days and was celebrated by processions in all the cities of the State. In Indianapolis the procession was headed by seventeen undertakers in the guise of crusaders bearing banners with the inscription "Disease Prevention Crusaders." A float of the Indiana State Medical Association depicted a physician alone in his office gazing at a sign bearing the words: "It's hard on us, but we're for it."

A Low Mortality Rate.—For the week ending October 3, the mortality rate for New York City was 10.58, the lowest yet recorded. This rate is 1.54 points lower than the corresponding week of 1913, an equivalent of a decrease of 165 deaths. All infectious diseases showed a decreased mortality, this being especially true of diphtheria, croup, typhoid fever, diarrheal diseases, and pneumonia. The death rate for the first forty weeks of the year 1914 is 13.81, as against a rate of 14.09 during the corresponding period last year.

Medical Society Elections.—INDIANA STATE MEDICAL ASSOCIATION.—The sixty-fifth annual meeting of this society was held in Lafayette on September 23-25, under the presidency of Dr. John F. Salb of Jasper. The following officers were elected: *President*, Dr. Frank B. Wynn of Indianapolis; *First Vice-President*, Dr. Edgar Cox of Kokomo; *Second Vice-President*, Dr. L. W. Smith of Wabash; *Third Vice-President*, Dr. W. J. Malloy of Muncie; *Secretary*, Dr. C. N. Combs of Terre Haute, reelected; *Treasurer*, Dr. D. W. Stevenson of Richmond reelected; *Delegates to American Medical Association*, Dr. C. H. Hood of Huntington, and Dr. Miles F. Porter of Fort Wayne. The next annual meeting will be held in Indianapolis.

MISSOURI VALLEY MEDICAL ASSOCIATION.—At the annual meeting of this society, held at Colfax, Iowa, during the third week in September, the following officers were elected: *President*, Dr. Granville N. Ryan of Des Moines; *First Vice-President*, Dr. A. E. Jing of Blockton; *Second Vice-President*, J. C. Waterman of Burke, S. D.; *Secretary*, Charles Wood Fassett of St. Joseph, Mo.; *Treasurer*, O. C. Gebhart of St. Joseph, Mo. The next annual meeting will be held in Omaha.

EIGHTH DISTRICT (OF GEORGIA) MEDICAL ASSOCIATION.—At the meeting of this organization at Athens, Ga., on September 24, the following officers were elected: *President*, Dr. Dan. H. DuPre of Athens; *Vice-President*, Dr. Stewart Brown of Royston; *Secretary*, Dr. E. M. Coleman. The next meeting will be held at Franklin Springs.

NORTHERN BERKSHIRE MEDICAL ASSOCIATION.—At the annual meeting held at North Adams, Mass., on September 22, the following officers were elected: *President*, Dr. Lyman Asa Jones; *Vice-President*, Dr. R. D. Canedy; *Secretary*, Dr. H. A. Bushnell; *Treasurer*, Dr. F. H. Howard; *Censors*, Drs. O. J. Brown, V. Adriance, J. H. A. Matte, A. K. Boom and C. W. Wright.

Obituary Notes. — Dr. WASHINGTON EMIL FISCHEL of St. Louis died on September 15 after a long illness. He was born in that city May 29, 1850, and was graduated from the St. Louis Medical College in 1871. After three years' study in Europe he began practice. He was immediately appointed instructor in the St. Louis (now Washington University) Medical School and in 1887 was made professor of clinical medicine. He was one of the founders and president of the medical staff of the Barnard Skin and Cancer Hospital. He was a member of the Advisory Board of the National Tuberculosis Association, the Council of the American School of Hygiene, the St. Louis Medical Society, the Missouri State Medical Association, the Verein Deutscher Aerzte, the American Medical Association, the Association of American Physicians, the St. Louis Medico-Legal Society, and the St. Louis Academy of Science.

Dr. JOSEPH M. HELLER of Osage City, Kans., died at his home in that city on September 19, from disease of the heart. He was graduated in 1877 from the Rush Medical College, Chicago, and practised at Osage City from 1885 up to the date of his death, with the exception of sixteen months at Coffeyville, Kansas.

Dr. B. E. MCSHANE of Milwaukee died at his home in that city on September 18, at the age of 44 years. He was born in Muskego, Wis., and was graduated from the College of Physicians and Surgeons, Chicago, in 1895.

Dr. STANLEY F. DUNCAN, of Quincy, Mass., died in that city on September 23, at the age of 27 years. He was a graduate of Tufts Medical School in 1912.

Dr. ROBERT WHITE died in Cambridge, Mass., on September 27, at the age of 91 years. He was a graduate of the University of Glasgow, a licentiate of the Apothecaries Hall of Dublin, and a member of the Royal College of Surgeons, London. He began practice in Boston in 1844 and retired in 1888.

Dr. JOHN CALVIN FLEMING, one of the oldest and best esteemed practitioners of Burlington, Iowa, died suddenly at the bedside of a patient on September 17. He was born in Huntington County, Pa., on November 24, 1848, and was a graduate of Jefferson Medical College, Philadelphia, in 1871.

Dr. SOLMAN MARKS of Milwaukee died in that city on September 28. He was born in Stockbridge, Vt., July 27, 1827, and was graduated from the Rush Medical College, Chicago, in 1853. He served in the medical corp of the Union Army during the Civil War, and at the close settled in Milwaukee. He was for a time president of the Wisconsin Board of

Health and was one of the founders of the American Surgical Association.

Dr. JAMES NEIL of this city died on September 28 at the age of 86 years. He was graduated from the New York University College in 1850 and had practised in this city for more than half a century. He was a member of the New York County and State Medical Societies.

Dr. ELLIS E. PAPPA of Youngstown, Ohio, died suddenly at his home in that city on September 23, at the age of 82 years. He was born in Bath, Me. He practised for many years in Detroit before going to Youngstown.

Dr. CHARLES FRANCIS GLADDING of Oakland, Cal., died on September 15, at the age of 58 years. He was born in Providence, R. I., and was a graduate of the California Eclectic Medical College, Los Angeles, in 1897. He had practised a number of years in Sacramento and also in Berkeley before going to Oakland.

Dr. C. L. INFIELD of Hudson Falls, N. Y., died in Troy on September 16, at the age of 54 years. He was a graduate of the New York University Medical School and had practised ever since graduation in Hudson Falls.

Dr. WILLIAM FRANCIS BYRNES of Washington, D. C., died suddenly at the home of his brother in Ware, Mass., on September 18, at the age of 67 years. He was a graduate of the Youngstown University School of Medicine in the class of 1873, and had practised in Washington for over 30 years.

Dr. HARRY NEWMAYER died at Philadelphia on September 28 at the age of 24 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1911, subsequently serving as resident physician in the Jewish Hospital and the Children's Hospital. He was a member of the Philadelphia Pediatric Society, the Philadelphia County Medical Society, and the Medical Society of the State of Pennsylvania and a Fellow of the American Medical Association.

Obituary.

LEMUEL BOLTON BANGS, M.D.,

NEW YORK.

DR. L. BOLTON BANGS, whose death occurred on Sunday after a brief illness, was one of the oldest and best known of what may be called the second generation of urological surgeons of this country. He was born in this city on August 9, 1842, and was graduated from the College of Physicians and Surgeons (Columbia University) in 1872. In 1880 he was appointed attending surgeon to Charity (now City) Hospital and in 1885 he became one of the attending surgeons to St. Luke's Hospital. In 1898 he was made professor of genitourinary diseases at the University and Bellevue Hospital Medical School, and held the chair in the same subject at the New York Post Graduate Medical School and Hospital. At the time of his death he was consulting surgeon to St. Luke's, Bellevue, City, St. Vincent's, Post-Graduate, and M. E. Hospitals. He was a member of the New York Academy of Medicine, of the Medical Societies of the County and State of New York, of the American Medical Association, and of the American Association of Genito-Urinary Surgeons, having been president of the latter in 1895. He was editor of the American Text-Book of Genito-Urinary Diseases, and had contributed largely to the literature of his specialty.

Correspondence.

SMEARS.

TO THE EDITOR OF MEDICAL RECORD:

SIR:—The commonplace is more important than the unusual. Consequently the writer of a monograph who takes too much for granted might as well have lost his understanding, so far as conveying the fundamental and elemental facts of his subject to the reader; his book is full of holes; incomplete and still-born. Volumes upon gynecological subjects have been written for many centuries, yet their everyday theme of leucorrhea still furnishes a hiatus between book and laboratory as no mind not specially trained could properly carry out their simple but unexplained order to "Take a culture." Personally I know how to take cervical smears because I was first instructed by word of mouth, but exploration of eight books on gynecology, two on bacteriology, and two on microscopy has failed to yield any information worthy of the name.

Such information in brief would be this: "Cleanse the urethra and cervix, pass a platinum loop to the internal os, and spread this secretion on a glass slide. Express the contents of the urethra and smear these on another slide." Of course a lubricant makes comfortable the introduction of a speculum but it spoils specimens. Vaseline, green soap, or other grease should be carefully wiped out with dry cotton because if not thus removed, from vagina and its introduced speculum, they mix with the secretion, give the smears a coat of grease and present to the laboratory man the problem of staining an oil with an aqueous solution. Should the lubricant contain a germicide, diagnosis and truth will be contradictions.

General surgeons are apt to sweep down the vagina with a finger and wipe the latter on a slide. Inasmuch as this contains the whole vaginal flora, overgrowth and all, it is not very good for staining purposes especially as the lubricant used on the finger is well mixed with the specimen.

The bacteriologist requires the platinum-loop-cervical sweepings with possibly an additional smear of urethral scrapings. More than this is valueless and may be a detriment.

DOUGLAS H. STEWART, M.D.

128 WEST EIGHTY-SIXTH STREET,
NEW YORK CITY.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

WOUNDED—RED CROSS AND AMBULANCE SOCIETIES—BELGIAN REFUGEES—ROYAL COMMISSION'S REPORT—SELECT COMMITTEE OF HOUSE OF COMMONS ON PATENT MEDICINES—OBITUARY.

LONDON, September 18, 1914.

THE King and Queen have spent a good deal of time at the hospitals where the wounded who have arrived from the war field are being care for. In the wards they conversed cheerily with the soldiers who were greatly delighted. Princess Victoria has also visited hospitals.

From various provincial hospitals information reaches me as to the reception of the wounded distributed among them. In one the nurse, showing a visitor around, expressed surprise that so many German wounded had been assigned to her care—a considerable percentage of her cases. The Red

Cross and St. John Ambulance societies pursue their work here and on the continent.

A Red Cross party led by Mr. Samuel Osborn went to Belgium soon after the outbreak of the war and a correspondent sends some remarks on the wounds which came under their observation. The great majority were in the extremities and a considerable proportion were healing so well that the men hoped to be able to return to the ranks. But too many bullet wounds were suppurating as if the first dressing had been defective. This was principally at the exit—the small entrance wound being usually closed as was the course of the bullet. Even in a base hospital carelessness as to asepsis astonished the correspondent who had previously supposed German surgeons to be exigent in this respect; while they were precise in some points, they were neglectful in others, *e.g.* after carefully washing their hands they would finger septic material. And it was the same with their instruments. Plaster of Paris splints seemed to be freely used, though the patients could not be kept under observation. The diet did not commend itself to my correspondent even in a base hospital, but perhaps the stress of war may have interfered with the supplies, though this is not alleged.

Among the numerous Belgian refugees who have fled from German atrocities to this country, not a few are sick as well as destitute and require medical care and nursing as well as food and shelter. The government has undertaken to meet their necessities and several large buildings have been taken by the Metropolitan Asylums Board for this purpose. The Alexandra Palace is one of these and has been prepared for the reception of some 3,000 persons, the work being under the direction of Dr. Herbert E. Cuff, the board's principal medical officer, who will have the superintendence of the sanitary and medical arrangements. Besides such official provisions considerable numbers of refugees are being hospitably entertained as guests in English homes throughout the country. Committees of associations and institutions whose trusts permit are also joining in the work and other committees formed *ad hoc* are extending a British welcome to the victims of the war.

On Monday the clerk of the board reported that the number of the refugees arriving was on the decrease and it seemed possible that the Alexandra Palace might not be required.

In a recent communication of the Royal Commission on Venereal Diseases, issued to the press, there is a reference to the association founded more than ten years ago under the name "The Alliance of Honor." As implied by the name, it is not a medical society, and the physical dangers of the social evil receive slight attention from its promoters compared with the moral question. At first many people did not expect the Alliance to succeed, but it has continued a steady effort in the cause of purity and its members have increased in many parts of the country to such an extent that about 500 branches have been established. The condition of enrolment in the membership is taking a pledge of personal purity. This of course implies an intention to propagate the object as an individual; the association as a body promotes it by public lectures and meetings, the circulation of printed matter, and practically any method of dispelling the lamentable ignorance that prevails as to the dangers that threaten the moral and physical health of those most exposed to temptation, showing them the degradation of any departure from sexual purity, but not ignoring entirely the risk of contracting disease, the effects of which may last for years and may be carried on to the next generation.

The report of the House of Commons Select Committee on Patent Medicines, which I mentioned to you two or three weeks ago, has now obtained general currency and proves to be an important document, inspiring the hope that it may be followed by legislation in the direction declared desirable. Having admitted the existence and sale of certain scientific preparations and some unobjectionable remedies for simple ailments, the committee pass on another class of secret medicines making "grossly exaggerated claims of efficacy," pretending to cure the incurable, injuring the sick by delaying proper treatment or containing dangerous constituents. In these and other ways they are said to be deliberate frauds as none "spring from therapeutic or medical knowledge, but are put upon the market by ignorant persons and in many cases by cunning swindlers, who exploit for their own profit the apparently invincible credulity of the public." This state of things they add "constitutes a grave and widespread public evil." In other countries and in our own Dominions there are legal restrictions to this iniquitous trade and a tendency to strengthen them may be recognized in many places, but in England we have no state officer or department charged with the duty of controlling the sale and advertisement of quack medicines. Successful prosecution for fraud in this matter is fraught with the greatest difficulty, though it may well be admitted as suggested in the report that "the public prosecutor has perhaps not sufficiently tested the powers of the existing laws in respect to such cases."

The traffic in quack remedies being thus uncontrolled is a condition which the committee pronounce to be intolerable. They declare that new legislation to deal with it, rather than mere amendment of existing laws, is "urgently needed in the public interest." Nevertheless, while pointing out the new laws they find necessary their recommendations include a number of amendments which, if secondary, are of little less importance.

Surgeon-Major W. H. Hayes has died at the age of 81. He entered the Indian Medical Service in 1855. He served through the Indian mutiny and was afterwards appointed to the deputy command of Singbkoon in Bengal. He retired in 1879, holding the Mutiny and the Empress medals. He has resided for some years at Faversham and represented that town on the Surrey County Council. He was also a member of several other public bodies.

Progress of Medical Science.

3. Drugs Used in General and Mental Hospitals.—D. Gregg states that the problems in medication at mental hospitals lie in the refinement of the use of drugs for purposes of elimination, in decreasing autointoxication, and in rectifying pathological action of the internal secretions. In eliminating substances from the body there is ample chance for skillful medication. There are cases needing mechanical relief by enemata, cases needing to have the fluids drained off by purges, and cases that are already desiccated and need more fluid, although still requiring relief from intestinal stasis. There are acute cases that may even need to be bled to reduce their fluids, or to have lumbar punctures done to lessen an excessive amount of cerebrospinal fluid. There are cases where autointoxication arises from infected teeth or tonsils, or from misplaced or adherent intestines. There are cases where presumably the thyroid, thymus, or pituitary glands, or the reproductive organs, are not functioning properly. In all these directions lie problems in medication for cases in mental hospitals. General hospitals have many lessons to learn from mental hospitals, especially in the management of the deliria. Not the least of these lessons is that depressants, stimulants, and restraint lessen, whereas baths, packs, and elimination greatly increase a patient's chance for recovery.

5. Recoveries at the Boston Psychopathic Hospital from the Standpoint of Nursing.—E. E. Southard analyzes a series of 100 recoveries at the Boston Psychopathic Hospital with reference to the particular share of the element of nursing in these recoveries. He finds that the component of nursing cannot be omitted from these recoveries, brief as was the time of the hospital stay of the majority of the cases. This is proved by the incidence of disorder of heat regulation (fever, hypothermia) in at least 3% per cent. of the cases. The special value of nursing, and particularly of hydrotherapy, stands out from the results of the treatment of alcoholic psychoses, which though they form only about one-ninth of the problem of first care, represent almost nine-tenths of the early therapeutic results. The recoveries in the so-called "recoverable" forms of insanity take too long to be represented in any numbers in this first hundred of recoveries, and it may be suspected that the average hospital stay of three to four weeks is not sufficient for recoveries in groups like manic-depressive insanity. The effect of psychotherapy as applied in the Psychopathic Hospital, is not a rapid effect. The percentage of syphilis in the recovered cases is exactly that of the total intake of the hospital, so that this factor cannot be said to influence treatment unfavorably. Some index of the activities of the after-care service is afforded by the fact that nearly half of the patients either resorted voluntarily or were brought to the out-patient department at one or more periods subsequent to the discharge. The need is apparent of nurses who shall build their psychopathic training on a sound basis of general hospital work.

8. Hysterectomy for Hemorrhage.—H. B. Perry and E. E. Thomas emphasize the facts that cancer occurs most frequently in the uterus, that it develops most commonly near the menopause, that its most prominent early symptom is abnormal bleeding, and that complete extermination of the growth is possible in any organ which can be removed before the rapidly growing condition spreads to the surrounding tissues. In women who have borne children and who subsequently develop cancer of the uterus it usually appears first in the cervix, while in women who have never experienced a full-term pregnancy, the disease more often attacks the fundus. Even eliminating cancer, undue hemorrhage near the menopause should be thoroughly investigated and followed closely, because of the possibility of any one of these conditions, which demand a hysterectomy for absolute relief. In disease of the adnexa the question often arises and is pertinent whether or not the uterus should be removed at the same time. The authors are firm in their belief, basing their opinion on the after-results of previous cases, closely followed and observed, that to leave a uterus after removing both tubes and ovaries would surely jeopardize that patient's future, comfort, and well-being; because a uterus that has been accompanied by diseased adnexa is of itself diseased and infected by the same pathological microorganism and will ultimately become an inert foreign body, or will prove itself a focus from which arise infections that may become general; or the organ may, because of the irritation that must exist, become the seat of malignancy. The removal of the uterus adds but little to the danger and shock of the operation, and should therefore be included in the complete operation.

1. Chondrectomy or Operative Treatment of Bronchial Asthma.—E. W. Andrews cites the following facts summarized by Garré, Tuffier, and others as somewhat convincing in pointing the way to chondrectomy of the first rib as a measure of great promise in the treatment of bronchial asthma: The want of development or ossification of the first rib cartilage causes loss of mobility of the upper chest aperture. The consequent constriction of the bronchi above causes catarrh and favors tuberculosis in the bronchial mucosa. A furrow often appears where the first rib crosses the apex. This may indicate injurious pressure. Asymmetrical stenosis causes curvature of the dorsal and cervical vertebræ. Spontaneous cure is sometimes seen in apical tuberculosis after natural pseudarthrosis of the first rib has occurred.

4. Studies in Intestinal Obstruction.—J. W. Draper concludes that the power of the liver to pair camphor and glycuromic acid is probably seriously impaired after duodenal obstruction. This can be studied by the method of Tollens, which, however, is cumbersome and may be faulty. Such decreased power of camphor-pairing is presumably an evidence of impaired liver function. This, however, is not reflected in the histological appearance, either grossly or microscopically. The decrease in the water-content of the tissues in duodenal obstruction is about the same as obtained after salivation by pilocarpin for four days or after fasting for seven. As this decrease produces no visible change in either case before euthanasia, it is reasonable to believe that it produces none in intestinal obstruction. The loss is ten per cent. The toxemia in duodenal obstruction arises from an interference with cellular

reactions of the intestinal epithelium. The toxins are at least in part eliminated from the colon and the stomach. If small intestine epithelial cells of healthy animals, are placed in the stomach of duodenal obstructed animals, such animals live nearly twice as long as not-fed control animals. This evidence is strongly opposed to the bacterial theory of origin of the toxins. In addition to the placing of jejunal and ileac epithelium in the stomach of postoperative obstruction cases, an emulsion of them should also probably be used in colonic irrigations for the same indication and purpose.

5. **Rovsing's Operation for Congenital Cystic Kidney.**—By F. B. Lund. (See MEDICAL RECORD, June 27, 1914, page 1193.)

8. **The Treatment of Pellagra.**—C. Voegtlin states that modern conceptions of nutrition and metabolism throw light on the beneficial effect of a liberal mixed diet on the course of pellagra. It is probably more than a mere coincidence that the population of that part of the world in which pellagra is endemic lives on a mainly vegetable diet. Economic conditions seem to influence in a general way the diet of people. A vegetable diet is as a rule less expensive, and persons in poor circumstances limit the consumption of the costly meats and the other animal food to a minimum. Attention is called to the fact that pellagra appeared in France soon after the reign of the first Napoleon, a period which was followed by extreme poverty in the country. France recovered from this economic depression in the latter part of the nineteenth century. With this change in economic conditions partly brought about through the introduction of the more profitable wine industry, pellagra decreased to such an extent that the disease is now very rare in that country. It is impossible to say at present that the food as such is the only factor in the production of pellagra, but even some of the adherents of the infectious theory do not deny that the one-sided diet may be one of the contributing factors in the production of this disease. The recent advances in the field of nutrition suggest new avenues of approach to the solution of this difficult problem. One will have to consider very seriously the following facts: (1) A deficiency or absence of certain vitamins in the diet. (2) The toxic effect of some substances, as aluminum, which occur in certain vegetable food. (3) A deficiency in the diet of certain amino-acids.

9. **Immunity in Tuberculosis.**—G. B. Webb and G. B. Gilbert state that guinea-pigs can probably not be immunized with virulent human tubercle bacilli of cultures from which ten bacilli can cause infection. The minimum lethal dose of different virulent cultures would appear to vary in number. The minimum lethal dose for a *Macacus rhesus* is possibly a little larger than that for a guinea-pig. It is necessary to be guided by the virulence of human tubercle bacilli as tested in the guinea-pig before the application to children. After four years two children each inoculated up to five times the lethal dose for guinea-pigs are still negative to the von Pirquet reaction. In monkeys the decrease of lymphocytes as indicated in differential blood-counts would appear to be more reliable in indicating tubercle infection than the tuberculin tests. Less than ten virulent human tubercle bacilli can infect a child.

11. **Salicylates in Acute Rheumatism.**—J. L. Miller notes that as salicylic acid after absorption circulates and appears in the tissues as a salicylate, it cannot act as a germicide unless the increased carbonic acid tension in the joint, the result of inflammation, reconverts it into salicylic acid. Statistics show that patients receiving salicylates are free from pain much earlier than those not treated. As the treated patients much more frequently relapse than the untreated, however, the total duration of pain in the treated and untreated patients may not be materially different. The period of stay in the hospital of patients receiving salicylates and of those receiving other forms of treatment is the same. Cardiac complications are not less frequent since the use of salicylates. In rabbits the prophylactic use of salicylates is of no value in preventing arthritis after intravenous injections of hemolytic streptococci.

1. **Open-Air Hospitals in War Time.**—R. Saundby calls attention to the fact that in the provision for the sick and wounded during the present war it is quite probable that the accommodation already made will prove insufficient and that large additional space will be needed. In the American Civil War and in the Franco-Prussian War the suitability of wooden buildings was abundantly proved, and with increased knowledge and confidence in the advantages of simple structures it is hoped that no more money will be spent upon structural alterations for hospital use, but that simple buildings will be erected for which there are many good designs to be seen in recently erected sanatoria. Open wards dispense with all need for considering methods of heating and ventilation; windows and doors are not required, but it may be desirable in some places to have sliding wooden screens to afford a certain amount of protection in stormy weather. Flooring may be made of asphalt or simple beaten earth covered with a thick layer of pine sawdust, which can be removed easily with a shovel, and which absorbs all damp to an extraordinary extent.

5. **Cardiac Fibrillation and Its Relation to Chloroform Anesthesia.**—J. A. MacWilliam states that in 1887 he advanced the view that many cases of sudden death depending on cardiac failure are due to the sudden occurrence of fibrillation in the ventricles, the function of the cardiac pump being thus destroyed. Ventricular fibrillation may occur at two phases of the action of chloroform: (1) In the early stage, this being by far the most common case; or (2) at a very advanced stage of the toxic action of the drug when the heart is greatly enfeebled and dilated. In some kinds of animals fibrillation may occur with great regularity as soon as the chloroform is pushed to a certain extent, weakening and dilating the heart. The special incidence of chloroform fibrillation on the ventricles as compared with the auricles is noteworthy. The latter commonly preserve their rhythmic action though they sometimes may fibrillate also.

8. **The Rôle of Carbohydrate in Nutrition.**—E. P. Cathcart as the result of his experiments concludes that both protein and carbohydrate, and almost certainly fat, are all essential for the physiological functioning

of the organism, and that these substances are all replaceable to a limited extent; in isodynamic or any other amount they are not isotamientic—that is, equally sparing. One is apt to overlook the fact that the active material of the body cells, the bioplasm, is a substance of unknown constitution; it is not simply a heterogeneous collection of more or less disintegrated food molecules. Such collections of foodstuffs as one recognizes at present in the cell are probably present there as reserves, not as currency, although Hopkins recently has advanced the view that "the integrity of the metabolic life of a liver cell is as much dependent on the coexistence of metaplasmic glycogen, however small in amount, as upon the coexistence of the nuclear material itself." But even this part of the food which is not utilized for structural repair may be divided into securities and currency. The currency is available at any moment, but the securities have to be liquidated—a comparatively slow process—before they can be used. Now, carbohydrate may be regarded as the currency which is readily available, and fat the security, but a security which cannot apparently be so fully liquidated as to take its place as a universal currency.

9. **History of Sugar in the Animal Body.**—J. J. R. Macleod discusses the controlling function which the liver exercises on the systemic blood-sugar. Since the time of Claude Bernard it has commonly been held that the surplus of dextrose absorbed during digestion into the portal blood is retained as glycogen in the liver, to be subsequently given up to the systemic blood, as this requires it to make good the losses due to tissue consumption. Although there is nothing to indicate that this view is not in general correct when the conditions are strictly physiological, yet there has accumulated a large amount of evidence which indicates that under abnormal conditions the stored glycogen may, in part at least, become removed from the liver otherwise than as dextrose. The author states that the local asphyxia produced in the liver cells by cessation of blood supply is followed by an increased discharge of sugar and lactic acid. In the case of the lactic acid invariably, and in the case of the sugar in nearly all of the author's experiments, the increase was most marked, not in the blood which escaped immediately after the removal of the clamp, but in that collected fifteen minutes later. One may therefore conclude that the local asphyxia of the liver cells causes sugar and lactic acid to be produced in very excessive quantities; and although in this fact alone there is no warrant for concluding that glycogen is the source, yet from numerous other experiments in which the glycogen has been determined one is almost certain that this is the case. Experiments by Embden and his collaborators have also shown that when the liver is profused outside the body lactic acid appears in the perfusion fluid, only provided the liver contains glycogen or the perfusion fluid an excess of dextrose. One may sum up by saying that the products of glycogen breakdown in the liver may comprise, besides dextrose, some colloidal substance and lactic acid.

Berliner klinische Wochenschrift.

August 24, 1914.

Influence of Thyroid Preparations on the Lungs.—Zondek and Frankfurther state that two methods must co-operate in order that our knowledge of the internal secretions shall advance. First we must study the alterations observed when the various glands have been eliminated; second we must investigate the consequences of injecting the active principles of the glands into the circulation, suddenly and in large quantities. The defect phenomena which follow extirpation of the thyroid are known clinically as myxedema and cachexia strumipriva. Again when thyroid substance is present in excess in the circulation we see clinically Graves' disease. Intravenous injections of thyroid substance (iodothyrin) cause a fall of blood pressure and a large, slow pulse, thought to be due to irritation of the vagus center in the medulla. The influence of thyroid substance on respiration has not been studied. The authors first sought to determine its action on the smooth muscle of the bronchi. Thyroid press-juice was tested on the cat and it was learned that various degrees of activity were present from slight contraction to total spasm. The pulmonary blood vessels were dilated. Individual susceptibility and an acquired tolerance were noted as present. Experiments showed that the activities of thyroid press-juice and iodothyrin could not be due to the contained iodine. As is the custom in these reactions, cholin was tested with the result that its possible pressure could not be accused of causing them. In order to eliminate the possibility of toxalbumin influence, ovarian press-juice, which is more toxic to cats than thyroid juice, was found to be without influence on the bronchi. Hence the action on the latter exerted by the thyroid may be regarded as specific; and it could further be shown that iodothyrin acts on the bronchial muscle directly and not by intermediation of nerves. The clinical bearings of this discovery remain to be studied.

Omental Torsion with Inclusion of a Loop of Intestine.—Fritsch states that the first reported case of omental torsion goes back only to 1882 and that up to 1910 at least 78 cases were known to be on record. The author has added a personal case and has found two more of recent date, so that the total is now at least 81. Of this number 63 were associated with internal "hernia" formation. Right sided cases predominate. Causal factors are appendicitis, pericolitis, tuberculosis, and malignant tumors. A type represented by the author's case comprised chronic constipation of aggravated type leading to pericolitis with omental adhesions. No symptoms develop until torsion happens, when with an intestinal loop "herniad" into the twisted mass, obstructive ileus promptly occur. Laparotomy, untwisting the mass and liberation of the so recently incarcerated intestine, are all the steps required, resection not being indicated under the circumstances.

Münchener medizinische Wochenschrift.

August 4, 1914.

Diagnostic Peculiarities of Cancer of the Body of the Stomach.—Baum states that in cancer of the stomach the personal history is vague, this being true especially of cancer of the corpus ventriculi. The tumor is palpable from without in from 63 per cent. to 67 per cent., and in cancer of the corpus in 53.1 per cent. only. The mechanical disturbance is striking and constant in cancer of the pylorus, but is as good as absent in cancer of the corpus. Lack of HCl in the gastric juice is not a constant symptom. It is present in about 80 per cent. of cases according to Hayem. Lactic acid and also the Boas-Oppler bacillus are seen only in retention and are therefore absent in cancer of the corpus. The *x*-ray picture can mislead as in both the negative and positive sense. It may be unable to disclose the presence of a cancer, and has proved to be a disappointment in the early diagnosis of the disease. Again the *x*-ray picture can simulate the presence of a cancer. The gastroscope according to Mayo has not yet been adapted to practical use. Of the various serum tests advocated from time to time only the von Dungern complement-fixation method gives fairly constant results and in the hands

of an expert gives positive results in about 90 per cent. The worth of the Abderhalden reaction is still *sub judice*. The only trustworthy diagnostic resource is trial laparotomy which when performed under local anesthesia is a safe procedure.

Biological Functions of the Corpus Luteum.—Seitz, Wintz and Fingerhut conclude their continued article on this subject as follows: menstruation is dependent on the function of the corpus luteum. The latter contains two substances of which one is the luteolipoid, and has a hemostatic property, so that if incorporated subcutaneously during menstruation, the period is abbreviated. The other substance, lipamin, is a lipoproteid—a leuthalbumin. In animal experiment it effects an accelerated growth of the genitals and when subcutaneously injected will bring about menstruation in the amenorrheic. The two antagonistic substances thus regulate the menses. Therapeutically the luteolipoid is of value in hemorrhages at puberty and in simple or functional menorrhagias. In climacteric hemorrhages it is of value only when the blood coagulation is delayed. It is inert when the bleeding depends on inflammation. In myoma it appears at first to increase the hemorrhage. When dysmenorrhea starts in with flowing the luteolipoid relieves the pain. The lipamin, to establish the menses, must be given over a long time. It ought to be given a good trial in genital hypoplasia.

Hyperleucocytosis from Cold.—Rovighi and Secchi have made a study of this phenomenon with the following results: in guinea-pigs moderate cooling of the body causes a peripheral hyperleucocytosis with notable preponderance of polynuclears. In the central blood the leucocytes and polynuclears are simultaneously diminished. Animals kept in cold air show a persistent peripheral hyperleucocytosis. If the cooling is carried too far there is a diminution in the number of leucocytes. In rabbits the same finds were obtained—hyperleucocytosis and leucopenia. The local application of cold can determine a local hyperleucocytosis. Persistent cold appears to cause destructive changes in the polynuclears, as a result of which their motility is diminished and viscosity increased. Hyperleucocytosis is practically a polynucleosis.

Münchener medizinische Wochenschrift.

August 11, 1914.

Treatment of Shot Wounds in General.—The new military supplement of the *Wochenschrift* (Feldärztliche Beilage, No. 1) is inaugurated with an article by von Angerer, written by request of the editor. The author served as volunteer surgeon in the Franco-Prussian war, and during the interim has practised as a civil surgeon. The differences between war and peace surgery are emphasized. On the battlefield there can be no primary wound disinfection. We can only apply iodine tincture, which the author prefers to "fixation" of the dirt with collodion, etc. The bullet tracts cannot be probed or explored with the finger, nor dilated, nor slit open. Neither antiseptic solutions nor drainage tubes are indicated. These limitations, however, are not applicable in certain wounds of soft parts with extensive openings for entrance or exit, and injury of vessels and nerves. We must now interfere, lay open the shot canal freely, extirpate all badly damaged tissues which would otherwise undergo necrosis, ligate vessels, suture nerves, remove all foreign material, irrigate with saline infusion, and tampon with iodoform gauze. In shot fractures, even if comminuted, fixed dressings can be applied, if the projectile has a small tract. With large wounds of entrance or exit and badly splintered bones we have to decide between resection and amputation. Wounds of the abdomen and thorax have to be treated with expectancy. Laparotomy on the battlefield is quite impracticable. Even trephining for wounds of the skull is done with some reserve. In infected wounds hydrogen peroxide is the antiseptic recommended. Bier's stasis and the hot air bath are used as routine measures. Balsam of Peru is an old standby. For hand asepsis rubber gloves are now indispensable, and hot water-and-alcohol disinfection of the hands when gloves are not worn. For disinfection of the operative field tincture of iodine has superseded older resources. For general narcosis the mixture of ether, chloroform, and oxygen is recommended. Infiltration and conduction anesthesia with ½ per cent. novocain are recommended for reduction of fractures and dislocations, for resections and amputations. With this concentration as much as 250 c.c. of solution can be used. The author, however, appears to limit its use to the upper extremity. For the lower limbs he regards lumbar anesthesia as adapted for military work, but hesitates to recommend it outright on account of serious drawbacks.

Origin of Hemorrhoids.—Schmincke concludes that essentially the hemorrhoidal disease consists in the dilatation of the finer branches of the veins in the hemorrhoidal region. This dilatation is something which increases progressively with advancing years. It is to be referred to the mechanical element in constipation, as a result of which the descending column of fecal matter presses against the small venous ramifications of the hemorrhoidal region. As a result of the simultaneous abdominal pressure these veins are unable to empty themselves with sufficient rapidity. The alterations which appear in the hemorrhoidal veins are explained by functional hypertrophy of the vascular wall with secondary insufficiency. Inflamed piles are due to bacillary infection.

Borderline between Normal and Pathological Temperatures.—Saathoff has devoted years to this subject and concludes that any reading over 37° C. (98.6° F.) cannot be regarded as normal. In other words it forms the superior limit of normal temperature. A single case of slight rise above this mark may have no significance, but if such is frequently noted it means that something is wrong. In a healthy subject leading a free, active life, an occasional rise up to 37.5° C. (99.5° F.) may have no pathological significance, yet a temperature of 99° F. occurring frequently may indicate the presence of some chronic infectious process, tuberculosis being the one first thought of. The 90 per cent. incidence of this affection in mankind should cause us not to disregard minimal uses of temperature.

Deutsche medizinische Wochenschrift.

August 13, 1914.

Treatment of Amenorrhea with Hypophysis Extract.—Kosminski refers to the unsatisfactory character of our treatment of this condition. Until recently our only aim has been to induce a pelvic congestion in the hope of bringing on the menses. At present we are endeavoring to make use of biological stimulation of the ovary. There has always been a small fraction of cases which are amenable to constitutional treatment. These occur in a variety of diseases, as chlorosis, tuberculosis, Graves' disease, etc. Animal experiment has taught that extirpation of the hypophysis is followed by atrophy of the genitals; so that the thought lay near that hypophysis extract might act as a genital stimulant. It is of course self evident that some correlation exists between the hypophysis and ovary, since ablation of both of these bodies causes results similar to each

other. In pregnancy we see marked alterations in the hypophysis, the ovary remaining inactive. After ovarian castration we also see enlargement of the hypophysis. In each case we note the development of alterations in the body at large, of the type suggesting acromegaly and obesity. Genuine acromegaly often begins with amenorrhea. In dystrophia adiposogenitalis we also see hypoplasia of the sexual organs, amenorrhea, and sterility. Hence when a woman develops amenorrhea we have to consider the possibility that the hypophysis may be at fault—that the hormone of this organ of which the office may be to regulate ovulation is secreted in defective quantities. In 1912 we see Fromme prescribing hypophysis extract for amenorrhea. He chose fat women with the idea that these betrayed an anomaly of internal secretion. Of twelve cases he reestablished the menses in five. Hofstaetter broadened the selection of cases by including hypoplasia, infantilism, atrophy following lactation, anemia, cachexia, and nervous states. He had good results in two-thirds of his cases. The author made a research into the subject at Abels' private clinic in Berlin, testing three preparations of hypophysis extract. In twenty-four cases treated his results were favorable in twenty. The selection of material agreed practically with that of Hofstaetter. There were included hypoplasia and late development (infantilism), subinvolution, obesity, preclimateric amenorrhea, neurasthenia, and hysteroepilepsy, and amenorrhea from exposure and adnexal disease. Despite the differences in etiology a few injections produced a flow of blood. The patients also began to feel better. In one case of infantilism in which ten injections had been given the woman flowed so much that ergot was injected. When suppression was due to cold or nervous influence one injection often sufficed. The remedy has thus far, Kosminski says, proved entirely harmless.

Results of Radiotherapy in Carcinoma.—Küstner and Heimann have been using this resource for eighteen months in the Breslau University Clinic for Diseases of Women. Ninety-eight cases of cancer have been rayed, including forty-four of inoperable cancer of the uterus and seventeen inoperable recurrences. There were also seventeen other cases of prophylactic raying and seven in which raying immediately preceded operation. Of the series of forty-four cases the majority had been pronounced inoperable after trial laparotomy. During the eighteen months period eight of the patients died. The indifference or fatalism of these patients is shocking as they make little effort to return for examination. In eight others treatment was a failure, either *per se* or because broken off by the patients. The remaining twenty-eight have all showed signs of improvement. In inoperable recurrences much greater doses must be used. Of the series of seventeen patients one is dead, two proved absolutely refractory, and the others all showed improvement, especially marked in two. Three operable cancers, occurring in two old and decrepit subjects and in a diabetic patient respectively were rayed with startling benefit, the growths having actually disappeared.

Deutsche medizinische Wochenschrift.

August 20, 1914.

Treatment of Threatening Hemorrhagic Diathesis, Leucemia, and Pseudoleucemia.—Grober refers to acute anemic states, other blood changes, failure of nutrition, paradoxic rise of temperature, acquired predisposition to sepsis, and other threatening conditions which follow both loss of blood and failure to produce red cells. Bound up in hemophilia and leucemia alike is the loss of coagulative power. Our time-honored resources in combating these conditions are too well known to require discussion, as are certain modern developments, as soft and medium *x*-rays for leucemia and pseudoleucemia, and adrenlin with a small cocaine addition in hemophilia. Of great promise for the future is serotherapy. Fresh blood serum and certain aqueous extracts of tissues have hemostatic powers. Quite recently a preparation of animal blood plates has been recommended as a hemostatic, to be applied either directly to bleeding surfaces or by intravenous injection. It is marketed under a trade mark name and the author has had no experience with it. He cannot speak enthusiastically of ergot, hydrastis, or calcium as hemostatics in hemophilia. A 10 per cent. solution of common salt injected intravenously in 5 c.c. doses has some value. There are numerous objections to gelatine in hemophilia. While repeated injection of blood serum has both prophylactic and remedial properties, the danger of anaphylaxis makes it necessary to use sera from several different animals.

Extract of Animal Blood Plates as a Hemostatic.—The state of war in Germany may be responsible for the fact that three articles in this number of the *Wochenschrift* are devoted to hemostasis. In addition to Grober's article abstracted above Juliusberger contributes an article on Fonio's discovery that animal blood plates obtained by fractional centrifugalization may be made to yield a blood coagulating substance. Unfortunately the method has been kept secret and the extract is marketed under a proprietary name. It is said to be an excellent styptic in surface hemorrhages. As for its intravenous use the thought lies near that it might cause thrombosis or embolism. The author has injected it into the circulation of patients suffering from hemoptysis and hematemesis with impunity and with good results. In one patient the weak heart action would have favored the development of thrombosis. The author has not yet had opportunity to test the remedy in hemophilia. Another article on this substance is by von Mutschenbacher and describes his experience with it in 100 cases of hemorrhage. He has used it upon the bleeding surfaces which result from separating peritoneal adhesions, etc., in which it is hoped to do away with the need of tampons; further in connection with transplantations and plastic work in which parenchymatous bleeding may prevent the full success of the operation.

Treatment of Ulcus Corneæ Serpens with Ethylhydrocuprein.—Schur relates his experience with this quinine derivative which was originally introduced as a promising chemotherapeutic agent in pneumococcus infections. He sums up as follows: One is justified in regarding ulcus corneæ serpens as a folk malady of the worst kind. Artisans and farmers are the worst victims as they are more subject to slight injuries. The rural contingent naturally come to consultation at a relatively late period. Ethylhydrocuprein, of proved value in pneumococcus infections, has shown itself to be one of our best resources against this evil. Naturally it is best to make a bacteriological diagnosis in a research of this kind, and the author had as material a series of 35 cases known to be caused by the pneumococcus. Of this number 30 recovered under ethylhydrocuprein alone. In the other five cases there were complications—perforation of the cornea or hypopyon—and although the cases were far advanced before treatment the drug did not prevent complications. In cases due to mixed infection—with diplo- or staphylococci—there was improvement; naturally with diplococci zinc must be used as a specific.

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

DIABETES AND GLYCOSURIA.

WHAT influence may be looked for when one or more deaths from diabetes appear in the family history? Dr. Otto May, at a meeting of the Life Assurance Medical Officers' Association of London, March 4, 1914, presented a study of 76,333 death claims in his company between 1901-1910. Of this number, diabetes caused death in 1,143, or 1.49 per cent. The family history of the 1,143 cases showed diabetes as the cause of death in forty-one, or 3.6 per cent. A control investigation of 1,143 other cases picked at random during the same period showed family history with diabetes in only twelve cases or 1.05 per cent. A comparison shows 53.7 per cent. of early deaths in the "positive" cases against 21 per cent. in the "negative" ones. A further analysis led Dr. May to suggest that: (1) There is a group in which there is a family tendency, the disease appearing at an earlier age and proving fatal more rapidly than the ordinary acquired type of the disease. (2) The diabetes with family tendency is more likely to appear in the male.

Deductions from such a small number of cases as that presented by Dr. May, while interesting, do not convince. It is almost impossible to find cases in numbers large enough to give conclusive results. For instance, the Medico Actuarial Investigating Committee recorded only 265 cases with two or more deaths from diabetes in the family history, with nine deaths, after analyzing the enormous amount of material at their command. However, statistics and clinical experience, though both are meager, lend strength to the view that there is an influence of heredity, and it may be assumed from a general view of the subject that the occurrence of two or more cases of diabetes in the immediate family history is a point to be considered in rating the risk.

The true diabetic condition seems to accompany some disturbance or change in the nervous system, pancreas, kidneys, or liver. The exact relation is unknown, as changes in these organs frequently occur without the presence of glycosuria, and at other times no change in them can be discovered when persistent glycosuria is present. Obesity plays an important rôle in persons who become very stout in middle life.

The liver and the muscles are the natural reservoirs of glucose, stored in the form of glycogen. The glycogen is reconverted into glucose and reenters the circulation in this form, when needed, to be oxidized for the production of heat and energy. It has been shown that the amount of glucose in the blood varies within the narrow limits of 0.1 and 0.2 per cent. When sugar is ingested in overwhelming quantities, the muscles and liver cannot hold all of it in the form of glycogen and the amount of glucose in the blood exceeds 0.2 per cent. Temporary glycosuria will then develop during the short time required for the consumption of the excess. The assimiliation limit of sugar is estimated to be about 150 to 200 grams of cane-sugar. It has been found, on the other hand, that sugar does not appear in the urine of healthy individuals after the ingestion of enormous quantities of starchy food, and that its presence under such circumstances should lead to the suspicion of a true diabetic condition. Osler has found no evidence to show that the diabetic individual forms any more sugar from a certain amount of food than does a healthy person, and thinks that all evidence points strongly towards the view that hyperglycemia is due rather to an underconsumption of glucose from a lowering of the power of the tissues to oxidize carbohydrates than to an overproduction.

Alimentary or temporary glycosuria should not be confounded with true diabetes, for, while glucose is not a normal constituent of the urine unless found immediately after taking an overwhelming amount of sugar, many of those subject to recurring attacks do not develop diabetes. It must not be understood by this that individuals with a history of repeated glycosuria are not underaverage risks, as it is well known they do not stand up against the shock of disease or injury as well as normal persons.

The Medico Actuarial Investigation gives a synopsis of the results in groups where an examination showed one finding of sugar in the urine on application or in which there was a recorded appearance within ten years. These results show actual deaths, 145; expected deaths, 104.48; ratio of actual to expected deaths, 103 per cent. This does not indicate an unfavorable experience and is explained by the fact that a particularly rigid selection was exercised. The interesting point is brought out, however, that death from diabetes in these cases was six times the regular rate. The committee was informed that the unpublished experience of a large company on under-average lives shows that where sugar was found in more than one specimen at the time of examination, there was a mortality of 200 per cent. Companies doing substandard business, therefore, have good grounds for refusing to insure risks in which glycosuria frequently makes its appearance.

Temporary glycosuria should be treated as follows:

A.—Cases with a history of glycosuria, not found on examination. These may be divided into two classes.

(1) When the glycosuria appeared at a remote date or on one or two occasions, the applicant may be accepted if he has had no treatment and has not been under restricted diet for urinary disturbances during the past year and if three specimens of urine obtained at different hours on successive days are normal.

(2) When the glycosuria has been found repeatedly for a number of years, especially if up to a recent date, the diet statement and three specimens should be obtained, but further precautions are necessary. A test meal is the most efficacious plan, the applicant taking a meal consisting of a liberal amount of starchy and saccharine food in the presence of a trusted and diplomatic representative of the company. Two specimens of urine passed one and a half and four hours after the meal should be obtained. If a test meal is impracticable the examiner should collect the specimens one to two hours after lunch or dinner without warning the applicant of the contemplated visit. The proposal to administer large doses of glucose should never be entertained, the dose advised being large enough to overwhelm the glycogenic function of the liver and cause glucose to appear in the urine of healthy persons as well as severe headaches at times.

B.—Cases without a history of glycosuria, but sugar found at time of examination. The diet statement and three additional specimens, if normal, will answer in these cases.

Book Reviews.

LEHRBUCH DER PSYCHIATRISCHEN DIAGNOSTIK. Von Privatdozent Dr. ADALBERT GREGOR, Oberarzt an der Kgl. Heilanstalt Dösen-Leipzig. Mit 7 Abbildungen. Preis, 4.80 marks. Berlin: Verlag von S. Karger, 1914.

THIS little book on the diagnosis of mental diseases is intended more especially for the student and general practitioner. It is of convenient size and helpful and written in a clear style. The general plan of the book is as follows: There are two parts, the first on general diagnosis of symptoms; the second, on the special diagnosis of the various forms of mental disorders. An outline scheme for the examination of patients is given together with a few brief examples of memory and intelligence tests. The space devoted to the important subject of personality study is only a page, which in view of recent studies, is disappointing. The classification of mental disorders followed by the author is based on the classifications of Ziehen, Kraepelin, and Roemer.

DIAGNOSTIK DER NERVEN-KRANKHEITEN. Von Prof. Dr. ALEXANDER MARGULIÉS in Prag. Erster Band, Allgemeiner pathologischer Teil. Mit 13 Abbildungen. Preis, 3 marks. Berlin: Verlag von S. Karger, 1914.

THIS, the first volume of Prof. Margulies' work, is on general pathology, and is modestly devoted to the student. The difficulties the student finds in the diagnosis of nervous diseases, every one agrees, are due for the most part to the lack of a thorough grounding in the anatomy and physiology of the nervous system. With such a knowledge acquired, diagnosis may be made much easier with the help of such a good work on the subject as this, although the book is more or less of the nature of a compendium. The author's arrangement of text of this first part, comprises ten chapters. The first chapter, on disturbances of motility, naturally treats of the paralyses, the spasmophilia, tremors, and ataxia, and contains several tables and drawings. The second chapter of the book is devoted to disorders of general sensibility; the third, to the significance of altered reflexes; the fourth and fifth chapters to brain diseases; the sixth chapter to the diseases of the cranial nerves; the seventh to diseases of the cord; the eighth, to the examination of the cerebrospinal fluid; the ninth, to disorders of the sympathetic; and the last chapter is on disorders of the internal secretions as affecting the nervous system. A careful perusal of part first of this work will enable the student to grasp the more practical issues of special diagnosis to be treated in the promised second part. The author is a well known Bohemian neurologist and writer. There are many books on the diagnosis of nervous diseases. This may prove to be one of the best.

PRACTICAL THERAPEUTICS INCLUDING MATERIA MEDICA AND PRESCRIPTION WRITING. With a description of the most Important New and Nonofficial Remedies passed upon by the Council on Pharmacy and Chemistry of the American Medical Association. By DANIEL M. HOYT, M.D., formerly Instructor in Therapeutics, University of Pennsylvania; Fellow of the College of Physicians; Assistant Physician to the Philadelphia General Hospital. Second edition. Revised and Rewritten. Price, $5.00. St. Louis: C. V. Mosby Company, 1914.

THIS volume differs in two respects from the majority of works on Materia Medica. In the first place it does not include all the preparations of the U. S. P.; and, further, it includes the most important preparations of the National Formulary and of the New and Nonofficial Remedies, of the A. M. A. This last part, which is called an "appendix," takes up about one-half of the book; and as this part can be purchased in its entirety for half a dollar or less, its inclusion here makes the present volume one of the most needlessly expensive volumes on the market. In the first half of the book we find a brief summary of the physiological action of the main drugs, with an indication of their clinical application; and, so far as it goes, it is fairly satisfactory. The last part needs more editorial care than has been bestowed upon it. Under the heading of Iodipin, we find: "Iodipin acts in the system similarly to the iodides, being taken up in a manner analogous to that described under bromipin, which see." This is quite allowable in the New and Nonofficial Remedies, which contains an article on bromipin; but in the present volume there is no article on bromipin, and so the reference is useless and annoying. The list of preparations and also the prescriptions should receive a thorough revision; at present they are a mixture of English and poor Latin.

PROGRESSIVE MEDICINE. A Quarterly Digest of Advances, Discoveries and Improvements in the Medical and Surgical Sciences. Edited by HOBART AMORY HARE, M.D., Professor of Therapeutics, Materia Medica and Diagnosis in the Jefferson Medical College, Philadelphia; Assisted by LEIGHTON F. APPLEMAN, M.D., Instructor in Therapeutics, Jefferson Medical College, Philadelphia, June 1, 1914. Price $6 per annum. Philadelphia and New York: Lea & Febiger, 1914.

THERE are five chapters in the present number of "Progressive Medicine." That on Hernia is supplied by W. B. Coley; that on Surgery of the abdomen, exclusive of hernia, by J. C. A. Gerster; that on Gynecology, by J. G. Clark; that on Diseases of the blood, diathetic and metabolic diseases, diseases of the thyroid gland, nutrition, and the lymphatic system, by A. Stengel; and that on Ophthalmology, by E. Jackson. All of the contributions are of a high order of merit; and we need only remind our readers that the present number contains Dr. Clark's annual summary of what has been written on the cancer problem.

THE PRACTICAL MEDICINE SERIES. Comprising ten volumes on the year's progress in medicine and surgery. Series 1914. Under the general editorial charge of CHARLES L. MIX, A.M., M.D., Professor of Physical Diagnosis in the Northwestern University Medical School. ROGER T. VAUGHAN, Ph.B., M.D. Volume I. GENERAL MEDICINE. Edited by FRANK BILLINGS, M.S., M.D. Head of the Medical Department and Dean of the Faculty of Rush Medical College, Chicago and J. H. SALISBURY, A.M., M.D., Professor of Medicine, Illinois Post-Graduate Medical School. Price, $1.50. Chicago: The Year Book Publishers.

THIS volume is one of two of the series devoted to general medicine. It is a valuable compend of the year's literature relating to tuberculosis, metabolic diseases and diseases of the lungs, heart, blood, blood-vessels, ductless glands, and kidneys.

Vol. II, General Surgery. Edited by John B. Murphy, A.M., M.D., LL.D., F.R.C.S., England (Hon.), F.A.C.S., President of the International Surgical Congress, London; Professor of Surgery in the Northwestern University; Attending Surgeon and Chief of Staff of Mercy Hospital and Columbus Hospital; Consulting Surgeon to Cook County Hospital and Alexian Brothers' Hospital, Chicago. Price, $2.00. It is hard to imagine a more interesting review of the year's progress in surgery than is given in this volume. The improvements in diagnosis, treatment and operative technique are fully explained. The author is frank in admitting that there are fields of surgery in which no real advance has been made. Reference is made to many interesting cases.

Volume III. The Eye, Ear, Nose, and Throat. Edited by Casey A. Wood, C.M., M.D., D.C.L., Albert H. Andrews, M.D., William L. Ballenger, M.D. Price, $2.00. Reviews of the most important papers of the year have been incorporated in this volume and as usual pertinent comments have been made by the authors. The book will prove a valuable addition to the library of those interested in the specialties to which it is devoted.

A HANDBOOK OF PSYCHOLOGY AND MENTAL DISEASE. For Use in Training Schools for Attendants and Nurses and in Medical Classes, and as a Ready Reference for the Practitioner. By C. B. BURR, M.D., Medical Director of Oak Grove Hospital (Flint, Mich.) for Mental and Nervous Diseases, etc. Fourth edition, revised and enlarged, with illustrations. Price, $1.50. Philadelphia: F. A. Davis Co., 1914.

THE present revision, the author states, concerns itself largely with those portions of the book of especial interest to medical men. Among these it is noted that a few studies have been made on a Freudian basis of certain states of paranoia and hysteria. The section on the "Management of Cases of Insanity from the Medical Standpoint" has been amplified; and a new section has been added entitled "Symbolism in Sanity and Insanity." It would seem, however, to the reviewer that the entire book, in its present form, is too advanced for the average nurse or attendant on the insane, and is better adapted to the medical student.

Diseases of Infancy and Childhood. Their Dietetic, Hygienic, and Medical Treatment. A Text-Book Designed for Practitioners and Students in Medicine. By Louis Fischer, M.D. Attending Physician to the Willard Parker and Riverside Hospitals of New York City; Attending Pediatrist to the Sydenham Hospital; Former Instructor in Diseases of Children at the New York Post-Graduate Medical School and Hospital, etc., etc.; Fellow of the New York Academy of Medicine. Fifth Edition. With 301 illustrations; several in colors, and 43 full-page half-tone and color plates. Price, $6.50. Philadelphia: F. A. Davis Company. London: Stanley Phillips, 1914.

In comparing this, the fifth, with the fourth edition of the same work one notes first of all the great improvement in its physical make-up. Containing nearly as many pages as the previous edition the newer volume is only one-third as thick. This change has been effected by the use of thinner and a better quality paper. The illustrations, besides, show up to better advantage. The text of the book has been greatly revised and improved. In dealing with the subject of nutrition the author now employs larger protein percentages and calls attention to the fact that high fat is now rarely fed. The new Berlin classification of gastric and intestinal derangements is given, food intoxication, weight disturbance, and decomposition being fully described. Articles on anaphylaxis, amebiasis, uncinariasis, acetonemia, and spasmophilia have been added. The illustrations on intubation which have been enlarged are superb, and cross-section illustrations, with the tube *in situ*, have been added. Vaccine and serum therapy are described and clinical cases are cited. There is an entirely new index. The chapters dealing with the infectious diseases of children are particularly well written. On the whole, this book ranks high among the large number of works on pediatrics available for the general practitioner and student.

Diagnostic Methods, Chemical, Bacteriological, and Microscopical. A Text-Book for Student and Practitioners. By Ralph W. Webster, M.D., Ph.D. Assistant Professor of Pharmacological Therapeutics and Instructor in Medicine in Rush Medical College, University of Chicago; Director of Chicago Clinical Laboratory. Fourth Edition, Revised and Enlarged; with 37 colored plates and 171 other illustrations. Price, $4.50. Philadelphia: P. Blakiston's Son & Co., 1914.

The publication of four editions of this work within a period of five years would be in itself a glowing testimonial, if it were not for the fact that the rapid extension and multiplication of diagnostic methods demand frequent revisions and additions to a work of this kind. The author has been alive to the need of maintaining the excellence of his book by keeping it strictly up-to-date. The present edition contains the following new matter: a discussion of the Negri bodies recently cultivated by Noguchi; Weisz's test for urochromogen; Dorrance's method for coagulation of the blood; Kowarsky's method for glucose in the blood; Levaditi and Manouelian's as well as Noguchi's methods for staining the spirochete in the tissues; Lange's colloidal-gold test for congenital syphilis; a discussion of the organism of anterior poliomyelitis recently cultivated by Flexner and Noguchi. There is considerable new matter with reference to the Wassermann reaction and the complement-fixation test in gonorrhea. Among other new topics are the Herman-Perutz reaction for syphilis and the application of Abderhalden's dialyzation method to the diagnosis of cancer and dementia præcox. A new chapter on clinical bacteriology has been added, in which are discussed the differentiation of the more important pathogenic organisms and also the methods of preparation of vaccines. One may criticise the use of the word "tubercular" instead of "tuberculous," in such expressions as "tuberculous pleurisy." On the whole the book contains strikingly few errors or omissions. It is well printed and handsomely illustrated and can be recommended without hesitation to the student and general practitioner.

I. K. Therapy, with Special Reference to Tuberculosis. By W. E. M. Armstrong, M.A., M.D., Dublin. Price, $1.50 net. New York: Paul B. Hoeber, 1914.

"I. K. Therapy" is the name used for Spengler's method of treating tuberculosis. For the benefit of those unfamiliar with bacteriological phraseology it must be stated that "I. K." does not stand for the German Jodekali or potassium iodide, but stands for the German "Immunkörper" (immune bodies). In his book just published Dr. Armstrong gives an excellent exposition of this interesting therapeutic procedure devised by Carl Spengler of Davos.

The book is divided into a number of small chapters treating on immunity, the nature of I. K., its mode of preparation and standardization, and the clinical evidences and practical administration of the product. The underlying basis of I. K. therapy is the fact that the red blood corpuscles are regarded as the great seat of manufacture and the storehouse of the immune elements, only a small fraction of the contents of this reservoir being found in the serous portion of the blood stream. Spengler and his pupil Armstrong compare the antibodies and erythrocytes to the deposit account, while those in the serum represent the current immunity account of the animal. The entire blood of an animal previously immunized against tuberculosis and other bacterial diseases is used in this therapy, of which this monograph of 75 pages gives an excellent idea. The work is recommended to all those interested in the specific therapy of tuberculosis.

Religion and Drink. By the Rev. E. A. Wasson, Ph.D., Rector of St. Stephen's Episcopal Church, Newark, N. J. Price, $1.25. New York: Burr Printing House, 1914.

This book is an attempt to answer the question, "What is God's will for us in the matter of drink?" This is the first examination of this question on so extensive a scale in the English language, and the answer is sought in the Church Universal. Part One, the Bible, discusses the testaments, side authorities, the Gospels, and Epistles. Part Two, the Church, epitomizes the question from the time of the primitive Church and the Fathers on through the temperance movement of the present day. Part Three, the Truth of the Gospel, religion and law, character, the new and living way.

Serology of Nervous and Mental Diseases. By D. M. Kaplan, M.D., Director of Clinical and Research Laboratories of the Neurological Institute, New York City; Serologist to the Montefiore Home. Illustrated; price, $3.50 net. Philadelphia and London: W. B. Saunders Company, 1914.

This is the first book on the subject by an American. Its general plan is as follows: There are four parts and a bibliography. The latter comprises seventy pages, showing the flood of serological literature which has gone before. The first part of the book is on Technology; the second, on the Serology of Nervous and Mental Diseases of Non-Luetic Etiology; the third, on the Serology of Nervous and Mental Diseases of Luetic Origin; and the fourth, on the Therapeutic Use of Salvarsan. Part I comprises an introductory history and considerations of anatomy and physiology, general considerations of the spinal fluid, and methods, and interpretation. Parts II and III show a large personal experience in the application of serology in the study of all of the common and most of the rare nervous and mental diseases. In part IV the directions respecting the use of salvarsan, and the precautions necessary to be observed, are stated specifically. The illustrations of the book are good and many of them original. The entire subject is presented in a clear and temperate way. The attitude of the serologist, says the author, should be one of wholesome skepticism. The entire Wassermann test, for example, should be regarded as of only secondary importance in making a complete study of a case of syphilis. The physician requires to know surely whether the reaction is positive or negative. Laboratories always obtaining a positive reaction should be looked upon with suspicion. "The careful worker will, in the course of time, consider a serum as positive only when it has resisted every attempt at negativation." The chief function of the serologist in the opinion of the author "is not so much to detect every syphilitic as to protect the non-luetic individual from a wrong diagnosis and useless treatment."

The chapter on the serology of the negative types (non-luetic diseases) is very instructive and interesting. We therein note for example that while a pleocytosis may occur, even without syphilis, it may be differentiated from a pleocytosis caused by syphilis, by methods described. Practical information will be found throughout the book but especially in the chapters on the serology of the syphilogenous diseases, and on salvarsan, and the book seems to be a safe exposition of the entire subject.

Society Reports.

NEW YORK ACADEMY OF MEDICINE

Stated Meeting, Held May 21, 1914.

DR. L. EMMETT HOLT, VICE-PRESIDENT, IN THE CHAIR.

THE subject of the evening was "Studies in Cancer" from the General Memorial Hospital.

The Cultivation of Human Cancer Cells in Vitro.—Dr. M. T. BURROWS presented this paper. He said that during the past few months in connection with the work of the General Memorial Hospital he had been testing a considerable number of human tissues by the culture method. In 1910, in association with Carrel, he had tested a considerable number of human malignant tumors, and in but few were any manifestations of life observed. Instead of an active migration and growth of cells as observed about fragments of many tissues of lower animals, the clots underwent a rapid dissolution. The digestion was often striking, involving a large part of the medium about the tissue fragment and taking place within a few hours after the preparation of the culture. In a few cultures of sarcomata the cells remained apparently alive, and migrated over the cover glass subsequent to the digestion of the medium. At a later time he had had the opportunity to test several pieces of tissue and had noted that the growth failed and the fibrin was rapidly digested about the fragment of tissue. This occurrence was more striking in human tissues than in those of animals. The tests of the past few months had been made with either autoplastic or homoplastic plasma, and the specimens of malignant tumors had been obtained from various hospitals. They had included lymphomata, a fibrosarcoma of the axilla, a recurrent chrondroma of the femur, two melanomata, several carcinomata of the breast, a thyroid sarcoma, and adenocarcinoma of the lymph glands of the neck and groin, cystomata, and a recurrent adenocarcinoma of the ovary. When possible the tissue was placed in plasma as soon as obtained, but in a few instances it had been carried a considerable distance and was not transplanted for one or two hours after it had been removed from the body. Whether this procedure was harmful had not been determined. As many successes and failures attended this treatment as when the tissues were cultivated at once. The tissue was cut in small fragments, placed on the surface of a cover glass, and covered with a layer of plasma. The slides were then inverted over the cover and sealed at once. The plasma had in most cases been used pure. In other instances it had been diluted one-half with isotonic sodium chloride solution. Control cultures of normal tissue of dogs and cats were prepared in a similar manner. About the fragments of the lymphomata, the chondroma, the fibrosarcoma, and normal connective tissue taken from the same individuals the reaction in the plasma was similar to that generally seen with the growth of similar tissues of other animals. The clot contracted, showing pitting of the lower free surface about the tissue border. The medium became more clear in this region, the fluid accumulating on its lower surface. No extensive or disorganized dissolution occurred. Fragments of the fibroma lived for eighteen days following several transplants. Connective tissue was grown from some of the carcinomata for a similar period of time while some of the fragments of the lymphomata and chondroma were kept as long as fifty days. No special effort had been made to preserve the tissue for a longer time. Spindle-shaped connective tissue cells were seen to wander out after each transplant until all the living cells had left the fragments. The cartilage matrix continued to spread or flatten out as long as living cells remained within it. Growth and division of a number of these cells was observed. From the fragments of the lymphomata both round and spindle cells migrated into the plasma, the latter predominating even about the fragments taken from the more cellular parts of the tumors. Similar growths were observed from the capsule of these tumors as well as the normal connective tissue of the neighborhood and from fragments of the chondroma. Active growth took place from fragments of cartilage. The fragments of the carcinomata had varied considerably in their ability to survive in the cultures. In but two cases had actual growth of the cancerous element been observed. In the other cases a rapid autolysis with or without active fibrin digestion was observed. This autolysis was most marked about the carcinomata of the breast and thyroid, and one of the ovarian tumors. The medium was digested slowly about many of the fragments of the melanomata. In the case of the melanoma as well as some of the carcinomata of the breast, the liquefaction was less about the smaller fragments, while in others it occurred about all the cancer elements. In all the cancers of the breast autolysis was rapid; in most of the fragments the cancer cells failed to stain at the end of twenty-four or forty-eight hours. Degeneration and fragmentation commenced in some of them subsequent to this time. Most of the carcinomata of the breast and thyroid when transferred at the end of forty-eight hours to new medium showed no further digestion of the clot. About the melanomata this digestion was not general but occurred in conical areas; it took place slowly in all fragments, and continued after many replants. Almost all the fibrous connective tissue fragments grew actively after five or six transplants. At the end of this time growth of this tissue ceased. Migration of epithelial cells was seen about an adenocarcinomata of the lymph glands as well as of an infected epithelioma of the mouth. The author then cited the details of the study of two ovarian carcinomata in which growth was observed. Since these experiments were performed he had, in association with Dr. Lewisohn, tested a carcinoma and a myoma of the uterus and two pieces of normal human tissue. The normal tissues were arteries and peritoneum, removed at a hernia operation. About the fragments of all these tissues, including small pieces of fat, the plasma was rapidly liquefied. The same results were noted in the earlier attempts, but were in sharp contrast to those performed during the winter months of this year. They had not yet been able to determine whether this fibrin digestion and tissue death was the result of some technical error, unidentified bacteria, of exposure, or some individual differences in the tissue. Differences in the plasma did not seem important. The rapid fibrin digestion could be ascribed, on the other hand, to pecularities of many of the epithelial cells. The failure of growth of many of these fragments might be further intimately associated with a failure of the tissues to spread and flatten out or a failure of the cells to liberate themselves from the firm fibrous tissue envelope. Active fibrin digestion was seen about fragments of normal intestine, thyroid, kidney, as well as about fragments of the bladder, ureter, and uterus. It might be observed about fragments containing endothelial cells such as arteries, peritoneum, pericardium, and pleura. Brain tissue showed a more active proteolytic power than fibrous tissue. In this connection it had been of interest to note that the pieces of pancreas tested did not digest the fibrin. This, when it did take place, had been seen only after a latent period of several days. Liquefaction was seen not only when cells failed to grow but during their growth as well. Leucocytes penetrated the clot along the narrow burrows, formed apparently through the digestion of the solid coagulum. The same was true of fibrous tissue cells. During the growth of this tissue a considerable quantity of fibrin might be dissolved. Epithelial membranes and tubes stretched through open tissue cavities between the tissue on one side and solid clots without. The cells survived for a time in many of the fragments where the rapid autolysis had been seen. The failure to stain did not mean that on removal to different environment these cells could not grow. It was further noted that the fragment lost after a time the ability to digest the fibrin. This decreased slowly, to disappear in or about forty-eight hours. It was found then that if the tissue was transplanted at the proper time from the liquefied plasma to fresh medium it would grow. This was illustrated by the experiments on an adenocystoma of the ovary. This tumor was planted in the plasma of a pregnant woman. At the first transplant the medium was liquefied after two hours. Fragments removed at the twenty-fourth hour to the plasma of a normal man reacted differently. From many there was an active growth of connective tissue cells as well as columns of cancerous elements. These experiments gave the first demonstration of the growth of human carcinomatous cells *in vitro*.

The Influence of Diet on Transplantable Sarcoma in Rats.—Dr. S. P. BEEBE said that the first paper published by them upon the question of the effect of diet in cancer had to do with the results obtained when carbohydrate was entirely eliminated from the diet.

They found that if carbohydrate was entirely eliminated there was a smaller percentage of positive takes; the tumor grew much more slowly and a larger percentage showed complete regression as compared with control animals on a full diet. In one experiment twenty-six animals were placed on a special diet and twenty-six controls on a full diet. They were all planted with the same tumor the same day. Every animal planted took the tumor. Of those animals on a special diet which contained no carbohydrate, two died from the tumor, four died from accident or unknown causes, twenty showed complete regression of the tumor. Of the twenty-six animals on the control diet containing carbohydrate, twenty-four died from the tumor and two recovered.

In order to obtain such effects, however, it was found necessary to prepare the animals by feeding them on a special diet for some time—from two to six weeks—before planting the tumor. If a special diet was begun on the same day of planting no difference could be observed between the two groups of animals. The most recent experiment had to do with other modifications of diet; it would be recalled that Mendel and Osborne had shown that the normal growth of a rat was markedly affected by the character of fat in the food. If a healthy rat was placed on a liberal diet containing fat in the form of lard he grew well for a time but finally reached a stage where growth was very slow and finally a loss of weight occurred even though he had an abundance of food. If, at this time, butter was substituted for lard, growth began again at once and continued in a normal fashion. If they were fed on butter from the beginning, there was no evidence of cessation of growth. They had made experiments to determine whether or not such an effect would be produced in tumors as was observed in normal animals. Their experiments had shown that butter was a very effective stimulant to the growth of the Buffalo sarcoma with which their experiments were concerned. The tumors grew much more rapidly in the animals having a butter diet. A much larger percentage of animals were killed by the tumor when the animals were fed on butter. In these experiments it had not been necessary to have a previous preparation of the animal in order to get the results indicated. The tumor growth in the animal fed on butter had been the most rapid and the tumor had reached a much larger size than in any animals that he had seen before. In some instances at the time of death of the animal the tumor mass weighed two and one-half times as much as the rest of the animal. In one instance the weight of the tumor dissected out at the time of death weighed 130 grams, compared with 51 grams of the body of the rest of the rat. In this instance it appeared that the diet favorable to the growth of animal tissue was also favorable to the growth of tumor tissue. Was it not difficult to reconcile such observations with the theory that these tumors had an infectious origin? They had made some experiments to determine the effect of cholesterol but were not yet ready to publish any conclusions.

It would be recalled that Mendel and Osborne had found that certain proteins which were incomplete, chemically, permitted maintenance but prevented growth. They had made some experiments with diet containing protein of this type and they had found that it was possible to maintain an animal in a fairly satisfactory condition of nutrition and yet prevent growth of the tumor. It had been possible to do this likewise in animals which had not been prepared for the planting of the tumor by a previous period of preparation on a special diet. A considerable number of features influenced the results which might be obtained in experiments of this character. Experiments had been made with other types of protein food but they were not yet ready to report results at this time. Enough had been determined, however, to indicate that the character of the diet influences the growth of the implanted tumor to a remarkable degree. These statements were based on their experience with the Buffalo sarcoma. They were not yet prepared to say what results might be obtained with other types of growths.

The Sugar Content of the Blood in Cancer.—Dr. S. R. BENEDICT and Dr. R. C. LEWIS presented this communication which was read by Dr. Lewis. He stated that this paper was based on experiments started three years ago at Cornell Medical College in which rats with transplantable sarcoma were fed on a non-carbohydrate diet. It was found that such rats showed an increased resistance to tumor growth provided that there had been a long preliminary period of non-carbohydrate feeding. There were a fewer number of takes, a greater number of retrogressions, and a slower rate of growth of the tumor in the rats on a non-carbohydrate diet than in those where a mixed diet was employed. When the diet contained carbohydrate the tumors grew luxuriantly. Far more striking results were obtained by Benedict on phloridzinized tumor-bearing rats. The animals were positively hopeless from the standpoint of spontaneous retrogression. Almost at once after the injection of the phloridzin the tumor began to soften. This was followed by a breaking down of the growth and finally by a sloughing of the entire mass. In all cases in which the rats were able to survive the treatment, that is, the effect of the phloridzin, growths as large as 20 by 21 mm. were made to completely disappear. In rats killed by chloroform following the treatment with phloridzin no sign of malignant tissue was found on pathological examination. In these phloridzinized rats there was a condition of complete carbohydrate starvation in that not only were the carbohydrates of the diet excluded but also that the carbohydrate arising in the body from metabolism of proteins was eliminated in the urine. This result might be due to a general malnutrition, which in turn was followed by the effect on the tumor, or it might be that the carbohydrates were *per se* necessary for the tumor growth. That the latter condition in reality existed found support in the literature. In their study of the blood sugar content of cancer patients they had developed a simple method of blood sugar determination which offered certain advantages over the older methods. One very marked advantage was that only very small amounts of blood were required. In general practice they used 2 c.c. of blood, although the sugar was as little as 0.5 c.c. could be determined. The method was based on the red color reaction obtained by heating dextra with a picric acid sodium carbonate solution. The blood was aspirated from a vein through a hypodermic needle into an Ostwald pipette, a little potassium oxylate in the tip of the pipette preventing clotting. The 2 c.c. of blood were discharged into a 25 c.c. volumetric flask, containing 5 c.c. of water. The pipette was rinsed once with water and the flask was well shaken to insure thorough mixing. In this manner the blood was laked, a matter of importance because the corpuscles contained some sugar that would otherwise be lost. Fifteen cubic centimeters of saturated picric acid solution were then added, the contents of the flask made up to the mark with water and then shaken. After filtration, 8 c.c. aliquots were measured out into large Jena test tubes for duplicate determinations. Two cubic centimeters of saturated picric acid solution and 1 c.c. of 10 per cent. solution of carbonate of sodium were added, as well as two glass beads and two or three drops of albolene, and the contents of the flask were evaporated over a direct flame until precipitation occurred. About 5 c.c. of water was then added to dissolve the precipitate; the contents were removed quantitatively to a 10 c.c. volumetric flask, cooled, made up to the mark, shaken, and then filtered through cotton into the calorimeter chamber. The color was compared with that of a solution of picramic acid which had been previously standardized, and from the reading the amount of sugar was calculated. The results obtained in this way compared very closely with those of the Reid phosphotungstic acid method. They had examined the blood of fifty-three hospital patients suffering from malignant growths, making about 200 examinations in all. The blood had always been taken at least three hours after the last ingestion of food. Examination of the bloods of twenty-five normal persons had shown a normal blood sugar content of 0.09 to 0.11 per cent. This figure agreed with those reported in the literature. Of the fifty-three cases, nineteen or thirty-six per cent. had shown a marked increase of blood sugar above the normal, ranging from 0.12 to 0.16 per cent., an increase of from 10 to 60 per cent. above normal. At least 49 per cent. of the cases showed a tendency at least to hyperglycemia. In no case was there a condition of hypoglycemia. In a few cases that had been followed for a long time, although the blood sugar content was normal when they were admitted to the hospital, there had been noted a steady increase with the progress of the disease, reaching a maximum just before death. No special relation between the pathology of the growth and the blood sugar content had been found but during more severe stages of malignant growth there was

certainly a marked hyperglycemia. This was not easy of explanation; it might be that the hyperglycemia was the result of a constant demand of the growing tumor for carbohydrate.

The Treatment of Cancer by Electrical Methods with and without Surgery and Radium.—Dr. ARTHUR F. HOLDING read this paper. He said that the electrical methods employed in the following series of cases were Roentgen deep therapy, effulguration (de Keating Hart) dessication (Clark), and thermopenetration. These therapeutic agencies were combined with surgery, radium, toxins, and vaccines, when such adjuvants were indicated. The results were due not so much to any originality of method as to the correlation of very excellent methods, which had already been described, but which were little understood and seldom utilized by the profession at large. Inasmuch as the cases had been treated only during the past eighteen months sufficient time had not elapsed to warrant a final statement concerning the successful cases. He concluded: (1) That incipient surface cancers could be cured. If they were superficial physical method should be employed. These in the order of their preference were massive doses of Roentgen rays, dessication, radium, destructive caustics, provided the more expensive equipments were not available. (2) Surface cancers, if tending to extend into the deeper structures, demanded surgical treatment, but should also be treated by preoperative massive doses of Roentgen rays, effulguration at the time of operation, and postoperative deep roentgeno- or radiotherapy. By the use of these adjuvants to surgical treatment the percentage of recovery in this class of patients had been materially improved. (3) Beginning cancer of the gastrointestinal tract could be diagnosed with accuracy by recently improved *x*-ray methods. (4) Inoperable malignant conditions cannot be cured by any method of treatment as the ultimate prognosis was 100 per cent. bad. The symptoms could usually be improved by electrical methods and radium. Much time might be lost and the patient's life endangered if one were deceived by the well-known superficial healing properties of radium as well as of the *x*-ray. The fact that lesions of the second degree of malignancy appear at first to improve under treatment indicated only for the first degree, gave a false sense of security and resulted only in therapeutic procrastination. Of the first degree of malignancy there were in their series thirteen cases, nine of which had been symptomatically cured under massive doses of *x*-ray, four were symptomatically cured with radium, and one by a combination of the *x*-ray and radium. Of the second degree of malignancy there were ten cases, four of epithelioma of the skin and six of carcinoma of the breat; all were treated by a combination of massive doses of *x*-ray, radical operation, and effulguration, followed by massive doses of *x*-ray or radium. Three of these patients were still under treatment, five had been discharged symptomatically cured, and two had discontinued treatment. All of these patients who had continued treatment were symptomatically well to date. Of the third degree of malignancy there were a total of 116 cases. Of these six were symptomatically well, twenty-four improved, thirty-eight unimproved, and thirty-seven dead. The only hope for internal growths was to diagnose them in their incipiency. The methods advocated in this paper were very expensive and hence if the work was to be continued sufficient money must be raised to carry it on. This meant for institutions proper endowment and for individuals adequate fees.

General and Experimental Therapeutics in Cancer.—Dr. RICHARD WEIL presented this paper in which he gave a brief survey of the ideals and objects of cancer research as they were now understood. In a paper published two years ago Dr. Ewing critically analyzed the results of cancer therapy and concluded that no single avenue of attack offered the royal road to success in cancer. He urged that in the union of therapeutic methods, in themselves incompletely effective, complete victory over the disease might be hoped for. As a preliminary to the combination of these various methods of attack, years of study devoted to the elucidation of the biology and the physiology of the cancer cell must be postulated. These principles had constituted the motive power of their work. In undertaking the treatment of any case of cancer they had accepted as axiomatic the principle that operation, wherever available, was the method of choice. This rule applied not only to all cases in which operation offered a hope of radical removal of all traces of the disease, but also of those borderland cases, in which radical removal was excluded by anatomical conditions. In all cases of both groups they had made a practice of reinforcing the operation by supplementary measures in order to obviate the possibility of implantation recurrence. They had made it a practice to follow the operation in each case by an immediate, thorough fulguration of every recess of the wound. This procedure was associated with no disadvantage of any kind that they had been able to discover. For a varying time after the operation the site was subjected to intensive *x*-raying. They believed that in this way they had been able to place in the category of curable neoplasms a group of cases which would inevitably have gone on to early recurrence. In addition they had used operative procedures as an adjuvant to other measures, and, finally, they had used it in combination with other modes of attack, as, for example, radium. Thus in a case of very extensive melanosarcoma of the face, both external carotids were ligated, and this procedure was followed by very extensive treatment with radium. The combination of these two measures resulted in the destruction and sloughing of the great mass of the tumor. One margin of the growth, between the internal and external carotids, progressed and eventually led to the death of the patient. The principle, however, was definitely established that vascular starvation was of tremendous importance in heightening the toxic effects of the radium emanations. The physical methods of treatment had been employed as extensively as possible. In connection with many of these procedures they had attempted to establish, by experimental investigations on rat tumors, their mode of action, and the limits of their applicability. It might be said of both the operative and the physical modes of attack that their effectiveness was sharply circumscribed and local in character. It was fair to demand of any rational therapy of cancer that it should be constitutional in character. Of such constitutional procedures there were at the present time only two which seemed to offer any promise or hope, namely, the methods of chemotherapy and immunology. In addition to these they had attempted to develop the metabolic treatment of the disease. They had studied the effects of colloidal solutions of a series of metals, including mercury, arsenic, copper, lead, and solenium upon human cancer. They had concluded that none of these substances were actually toxic to the cancer cell and they had therefore discarded their use. They had also studied the localization of a large series of synthetic dyes in rat tumors. Although it had not been possible to discover any dye possessing a distinctly specific affinity for neoplastic tissue, it was found that certain dyes of the diazo group lodged in larger amount, and remained for much longer periods, in the tumor tissue, than in the normal tissues of the body. Following this lead they were fortunate enough to secure the assistance of the Department of Organic Chemistry of the University at Ithaca, which had put at their disposal a series of compounds of arsenic, formalin, and other substances, with the diazo nucleus. The final report on the effectiveness of these and allied substances had not been made. The use of toxins as elaborated by Coley, was to be regarded as a form of chemotherapy, even though the chemical constitution of the agent was entirely unknown. Closely related to the chemical methods was the attack upon cancer by the alteration of the metabolic environment. There were thus far no cures ascribed to it, but the clinical study of its effectiveness was only in its beginning. The immunological, also called the biological, methods of treatment seemed, in some ways, to offer the most hopeful promise for the future. These were the methods in which experimental investigation had been most fruitful. This method consisted of passive and active immunization. The latter method was credited in the literature with certain apparently indisputable cures. They had made a fairly extensive use of vaccination, not only alone, but in combination with the *x*-ray and other procedures. Although it was too early to form a definite judgment as to the final results, there could be no doubt that vaccination did in many cases produce very marked shrinkage of the tumor, which had, in some instances, gone on to complete disappearance. Only a prolonged study could show whether these successes were only apparent or whether they were real and lasting. By a concentration of all the forces, both of the laboratory and of the clinic, upon the elucidation of the cancer problem, it might be possible to secure some advance in the

cure of the condition, but it was vain to expect early or brilliant triumphs. It is fitting that the work of the memorial Hospital in radium therapy should be discussed somewhat more in detail. Owing to the interest and generosity of Dr. Douglas they had had the advantage of a supply of radium which was adequate to their immediate needs, and which was undergoing constant augmentation. They had felt, however, that the study of radiotherapy could not profitably be conducted along the same general lines as those pursued in the past. It appeared evident that purely clinical studies could not by themselves serve to dispel these difficulties and dangers which had in the past beset the use of this agent. The therapeutic work, therefore, was now carried on in conjunction with the service of a physicist who was attached to the staff, Dr. Bosworth, and already the effectiveness of such a combination was evident in the improvement of their clinical methods. Previously they had labored under the same difficulty which confronted all workers with radium, namely, the limitation of the apparatus and dosage consequent upon the provision of fixed amounts of the element in sealed containers or applicators. The method was of course extremely rigid and inelastic. The installation of an apparatus for the collection of emanations at once dispelled the difficulty. They were now in a position to order in advance any desired amount of radium emanation in a tube of specified size and caliber. Thus at one stroke the limits of its clinical use were enormously enlarged. Time did not permit a detailed analysis of the results of their work with radium. In general its use in superficial epithelioma had been most satisfactory. The effect on malignant tumors of other types were, however, not encouraging. Occasionally they had witnessed the disappearance of solid tumors under its use, as for instance, a mixed tumor of the parotid, but such fortunate results were rare events. Possibly wide experience in the use of the rays and their combination with other agents would enlarge the field of their usefulness.

SECTION ON SURGERY.

Stated Meeting, Held May 1, 1914.

DR. JOHN DOUGLAS, SECRETARY, IN THE CHAIR.

Extirpation of the Parotid Gland for Carcinoma.—Dr. GEORGE H. SEMKEN presented this patient. She was fifty-three years of age, and came under observation on December 18, 1913. Her family and previous personal histories were negative. Six months previously she noted a tumor in the left parotid region. This had increased in size at a moderate rate, but had given rise to no subjective symptoms. Examination revealed a hard, rounded tumor in the posterior parotid region, 4.5 x 5.5 c.m. in size. Its surface was nearly smooth. The ear was elevated in its lower part. The overlying skin was unchanged. The upper cervical lymphatic glands were enlarged. The mass was but slightly movable. There was no facial paralysis. Operation was performed four days after at the German Hospital under general anesthesia by the ether-oil rectal method of Gwathmey. Beginning in front of the left ear, a vertical incision was made, extending down to the anterior border of the sterno-cleido-mastoid muscle, continuing then along this border to the midlaryngeal level. From this point it curved forward and upward, ending in the anterior sub-maxillary region. Two supplemental incisions were made, one proceeding from the upper end of the incision and extending along the zygoma, the second extending horizontally backward, under the ear and across the mastoid region. The skin flaps thus outlined were reflected, and the parotid and upper cervical regions well exposed. The parotid gland, the submaxillary structures and the upper cervical lymphatic structures were removed by block dissection. So far as could be determined, the carcinomatous area was never entered. The recovery was uneventful. An unavoidable, unpleasant sequel was the facial paralysis, consequent upon the division of the seventh nerve. There was also some edema in the cheek, owing to the removal of the cervical lymphatic structures and consequent stasis.

Flap Transplantation for Extensive Cicatrix Deformity of the Hand.—Dr. SEMKEN also presented a girl seventeen years of age, who washed her gloved hands in benzine to clean the gloves, and then, not realizing the hazard, attempted to light the gas. Her hands were severely burned, and it required many months of treatment to heal them. The large loss of skin, the keloidal tendency in most of the scars, and the subcutaneous contractures produced an extensive cicatrix deformity which made it impossible for the patient to resume her occupation as stenographer. The cicatrix of the left hand (which was the subject of this operation) was distributed as follows: A bluish, keloidal cicatrix surrounded the wrist like a bracelet. On the dorsum it extended broadly from the wrist to the bases of the fingers, continuing in long bands down the fingers as far as the nails, most markedly on the middle and ring fingers. The webbing was not injured, and the damage to the distal part of the palm was negligible. Operation was done at the New York Skin and Cancer Hospital. The dorsal part of the cicatrix was removed by careful dissection, from the wrist to the fingers, the first phalangeal segments of the middle and ring fingers being included. The dissection extended laterally from the radial edge of the palm to the ulnar margin of the palm, but involved the dorsum alone. A flap was then outlined on the right lateral chest wall, corresponding to the wound on the dorsum of the hand. The pedicle of the flap was at its lower border. This flap was then raised, temporarily turned down, and the chest wound was closed, partly with sutures and partly with Thiersch skin-grafts. A small dressing was applied to this area. The left hand was then placed upon this dressing, the flap was placed upon the dorsum of the hand and carefully sutured in place. A fixation dressing of plaster-of-paris maintained the position during healing. One week later the second stage of the operation was carried out. At this time the flap had become firmly attached to the hand and was receiving some blood supply from the new site. The further procedure was as follows: The hand was gently supinated to bring the palm into view without tearing the new flap attachment, and a careful dissection was made to remove the palmar-wrist cicatrix. This wound was provisionally covered with saline gauze, and the hand was replaced in the position it had occupied, flat against the chest. By a vertical incision at each end of the pedicle the flap was further outlined and then raised. By lowering the hand and bringing it into full pronation it was possible to roll the wrist and hand into the continuation of the flap, thus adapting the latter to the wound on the palmar surface. As was evident, the pedicle was retained at the lower border. After careful suture of the flap a new fixation dressing of plaster-of-paris was applied. The chest wound had been closed with suture and Thiersch graft. Her recovery was uneventful. The division of the pedicle was begun nine days after the second operation and was completed two days later. The result of the operation was that the scar tissue had been replaced with normal skin and subcutaneous tissue. An adequate blood supply was soon established, and the flap had also received a nearly complete nerve supply. So far as the patient could judge, sensation was as acute in the flap as it was in the uninjured hand. A slight swelling still demonstrated the incomplete lymphatic apparatus.

Supernumerary Ureter Opening Extravesically.—Dr. HENRY DAWSON FURNISS reported this case. The patient was a girl, twenty years of age, whose menstrual history was negative and who had never been pregnant. As long as she could remember she had been wet with urine day and night, and yet voided naturally once or twice a day. The patient was well formed and showed no stigmata of degeneration, nor abnormalities of the genital organs. An examination was made with the idea of finding an abnormally opening ureter, and was conducted as follows: Ten c.c. of 1 10 of one per cent. solution of indigo-carmine was injected intravenously and the patient was then cystoscoped. A normally situated ureter excreting urine in a normal manner was found on either side. The whole urethra and the entire vagina, with the patient in the knee-chest posture, was inspected without discovering the source of the leakage. Still suspecting that the condition was as suspected, the vagina was plugged with wet cotton tampons and wet cotton applicators were placed in the urethra extending just to the vesical sphincter of the urethra, and a pledget of wet cotton over the vestibule of the vagina. After waiting fifteen minutes these were removed, and it was found that the cotton over the urethral orifice was stained faintly blue, while the ones from the urethra and vagina showed no discoloration. Close inspection failed to show the ureter until the patient strained in moving, when there was a discharge of a few drops of fluid from a minute orifice

in the median line just at the lower edge of the urethral opening. From this was obtained in ten minutes a faintly bluish colored fluid of a low specific gravity. The specific gravity was not noted, nor was an estimate of the urea percentage made. It would have been interesting to have had injected all three ureters with collargol to have seen their relations to each other and to the kidney pelves, but this was abstained from as it would have been of no benefit to the patient, and one ran the danger of causing infection, supernumerary ureters being especially susceptible. Operation was performed on June 26, 1913, at the Post-Graduate Hospital. Under ether anesthesia the supernumerary ureter was catherized for four inches with a ureteral catheter. An incision was made over it on the under surface of the urethra, but unfortunately, the incision went into the ureter itself, which was thin walled and dilated to the size of a pencil. This dilatation involved only the distal one inch of the ureter. Thinking the whole ureter would possibly be dilated and that there would be difficulty in dissecting it out, a urinary sound was put through the urethra, which was made to bulge the bladder just over this ureteral sac. An opening between this sac and the bladder was made, and the mucosa of the ureteral sac and the mucosa of the bladder sutured together. Next the floor of the ureteral sac and the external orifice of the ureter were closed with fine catgut, thus producing a fistula between the bladder and the ureteral sac into which the ureter emptied. The vagina was closed over this with sutures of silkworm gut. A retention catheter was put into the bladder and removed on the fourth day, but following the operation the patient had the same leakage as before. The patient was operated on again on July 11. It was found that the leakage occurred from the posterior end of the incision. A pararectal incision was made through the left sulcus of the vagina; a catheter was then passed into the ureter and the ureter was dissected out for an inch and a half. It was surprising how easily this was done and to see how thick the ureter really was, being here the size of a goose's quill. A uterine sound was passed through the urethra and made to bulge the bladder just behind and to the inner side of the normal opening of the left ureter. A small incision was made in the point of the sound which was then pushed into the vagina. A suture was passed through one lip of the ureter, tied to the sound, and in this way the ureter was pulled into the bladder for a distance of three-quarters of an inch. This suture was withdrawn through the urethra and with a needle was anchored just outside the clitoris. One fine suture of plain catgut was passed through a portion of the muscular wall of the ureter and the opening into the bladder, and the vagina closed over this with interrupted sutures of catgut. Following this operation there was not a bit of leakage. Painful urination and a rather severe cystitis followed the operation, but the patient made a good recovery. A subsequent cystoscopic examination showed the ureter implanted as a small, round opening just behind the inner side of the normal ureter.

Total Extirpation of the Tongue for Carcinoma.—Dr. FRANZ TOREK presented this patient and the specimen, which showed the ulcerated part of the carcinoma extending from the left edge of the tongue to the median line, the infiltration having progressed beyond midline. There was extensive involvement of the glands in the submaxillary and cervical regions on both sides. The glands from one mastoid process to the other and down to the clavicles were removed and the lingual arteries tied under general anesthesia. The tongue was extirpated at a later sitting, four weeks ago, under local anesthesia, novain one-half per cent. and suprerenin being employed. The operation was performed without the use of any auxiliary incision either through the cheek or jaw. If the floor of the mouth was not yet involved, or but slightly invaded, the total extirpation of the tongue could be performed through the mouth. A suture was carried through the tongue to serve for making traction. The mucous membrane at the floor of the mouth was divided close to the jaw, then the muscles under the tongue were divided with scissors, beginning with the genioglossus. The division of this muscle liberated the tongue considerably, and when the hypoglossus had been cut on each side the tongue could be drawn forward so far that its ablation close to the hypid bone was not difficult. In cases with extensive involvement of the floor of the mouth it was not advisable to operate without dividing the jaw. There was a distinct advantage in performing the extirpation of the tongue under local anesthesia, the chances of aspiration pneumonia being thereby much reduced. The operation was also facilitated, inasmuch as the suprarenin contained in the local anesthetic, in conjunction with the preliminary ligation of the lingual arteries, rendered the operation practically or entirely bloodless. Local anesthesia might also be employed where the jaw was divided. The patient had no difficulty in swallowing soft and solid food; it was a little more difficult for him to drink water. He was able to speak very distinctly and he gained considerably in weight.

Vicious Circle of the Colon After Cecosigmoidostomy.—Dr. HERMANN FISCHER presented a woman in whom a partial exclusion of the colon had been done by another surgeon for symptoms of chronic partial obstruction of the colon caused by adhesions at the splenic flexure. After the operation all her symptoms were aggravated. She complained of constant pain all over her abdomen, especially along the course of the colon. The rumbling of gas in her intestine was so loud that it could be heard at some distance. This noise was especially annoying and disturbing during the night. The chronic constipation she had been suffering from before the operation became worse, so that she was compelled to resort to daily high enemata, with often very little result. She was exhausted and highly neurasthenic. A series of *x*-ray plates showed the following condition: There was a complete obstruction of the colon at the splenic flexure, no bismuth passing into the descending colon at any time. Some of the bismuth passed through the anastomosis into the sigmoid flexure. The bulk of the bowel contents, however, traveled the old way through the cecum and ascending and transverse colon to the obstruction at the splenic flexure. From there it was pushed back again by an anaperistaltic wave into the cecum. It was clear, therefore, that the bowel was not properly drained by the cecosigmoidostomy and a state of vicious circle had developed. At the operation it was found that the colon at the splenic flexure was twisted around its long axis and held in this position by dense adhesions, which had their origin on the lateral abdominal wall near the spleen. These were cut and removed, after which procedure the gut unfolded itself. The wall of the intestine was normal. Ascending colon and cecum were enormously dilated to the size of a large man's arm, their walls hypertrophic; the cecum was filled with soft feces and was crowded into the pelvis. The base of the cecum was bent upward and the splenic flexure was lying on top of it, making it impossible for the cecum to empty its contents properly through the anastomosis. The dilated cecum and ascending colon were removed up to the hepatic flexure. The opening in the sigmoid flexure was closed and an ileocolostomy done. The patient made an uneventful recovery. She had now a spontaneous movement every day and felt well, aside from some dyspeptic symptoms she had always complained about.

Relaxation of the Diaphragm.—Dr. HERMANN FISCHER made this report. This condition was a very rare one; there were only twenty-three cases reported in the literature. By relaxation of the diaphragm they understood a thinning out and fatty degeneration of the fibers of the muscle and a bulging of the same into the thorax so that the diaphragm reached up to the third or even second rib. This condition had been found so far invariably on the left side, with the exception of one case, in which it was found on the right. The stomach and colon lay before the diaphragm in the thoracic cavity. The etiological factor was not clear. Usually relaxation of the diaphragm was considered to be a congenital condition, but there were cases on record in which the anomaly had been acquired, trauma playing some rôle. This peculiar anomaly had become of surgical interest on account of its difficult differential diagnosis from a diaphragmatic hernia, in which disease surgical interference was sometimes necessary. *X*-ray examination had failed to make a positive diagnosis in these cases, and some had been diagnosed by *x*-ray as diaphragmatic hernias, which later turned out to be a relaxation of the diaphragm, and *vice versa*. The case which he had the opportunity to study in the German Hospital through the kindness of Dr. N. Stadtmueller was of special interest, as it developed during convalescence from a double pneumonia and typhoid fever under their eyes and that it was the first case in which the diagnosis was made by them without a doubt *in vivo*, by a probatory thoracotomy under intratracheal insufflation.

Intrapleural Pneumolysis in Pulmonary Tuberculosis.—Dr. Franz Torek said that it seemed generally to be acknowledged that the pneumothorax treatment of tuberculosis of the lungs was of value in combating the disease, inasmuch as it met the indication of giving the diseased organ more or less functional rest, of permitting the fibrous tissue to contract about the tuberculous foci, encapsulting them, and of causing lung cavities to collapse, discharge their contents, and in some cases to become obliterated. The pneumothorax treatment would not bring about these results under all circumstances, but only in suitable cases. In many cases of pulmonary tuberculosis the adhesions were so extensive that the pleural cavity was practically, if not completely, obliterated. In such cases it was plainly impossible to inject the nitrogen. In other cases, where only a limited portion of the pleural cavity was free from adhesions, the collapse of the lung produced by the injection of the nitrogen would be too slight to be of much, if any, value. In many cases, again, the *x*-ray revealed the fact that while the lower part of the lung collapsed to a slight or fair degree the upper portion remained entirely uninfluenced. In these cases the operation of extensive removal of the ribs on the affected side, from the first or second to the tenth or eleventh, according to Friedrich and others, had been practised, the object being to cause the entire chest wall to collapse with the lung. The trouble with this procedure was that patients who were in a condition to be aided by pneumothorax were unable to stand such an extensive operation. The deaths after this operation occurred either primarily as a result of shock, or, secondarily, as a result of the instability of the mediastinum. The problem had presented itself to the writer whether the collapse of the diseased lung could be accomplished by an operation which would not only be simpler than that referred to above but would also preserve the bony frame of the chest. The solution appeared to him to be found in the intrathoracic separation of the adhesions between the visceral and the parietal pleura, interpleural pneumoclysis, as he had termed it. Tuffier, in resecting the apex, separated that portion of the parietal pleura which covered the apex from the chest wall, but left the parietal pleura attached to the visceral pleura. Baer liberated the costal pleura over the apex in a similar manner, without, however, resecting the apex. This method of operation was followed: Anesthesia was conducted by intratracheal insufflation or other methods of differential pressure to guard against the possible occurrence of respiratory accidents. An incision of ample dimensions, about six inches, was made in the sixth or seventh intercostal space, at the posterolateral aspect of the chest, down to the pleura, and after all hemorrhage had been stopped the pleura was opened. The patient was now placed with the head low, so that if in the course of the manipulations of the lung the contents of a cavity were expressed they might run into the mouth and not into the opposite lung. The adhesions between the two layers of pleura were then separated. This was accomplished by introducing at first only the tip of the finger to separate the adhesions in the immediate vicinity of the incision, the ribs being held apart by retractors. The separation then proceeded further and further, until finally the whole hand was introduced into the chest in order to liberate the more distant parts of the lung. In the course of this procedure bands of adhesions might be encountered that were so dense as to require division with the scissors. When the separation of the adhesions had been completed the lung would collapse as much as the degree of its infiltration would permit; it was allowed to remain in this state of collapse, and was not inflated before closing the thorax. The pleural cavity was closed without drainage. The two ribs which had been spread apart were brought into apposition by pericostal sutures of silk or chromicized catgut, the muscles were sutured with catgut, and the skin with silkworm gut. Following this operation there was none of the pain that was often experienced in the ordinary pneumothorax treatment after the injection of nitrogen. After this operation no tugging on the pleura could take place. Subsequent treatment was similar to that given in the ordinary pneumothorax method. Physical examination, especially with the *x*-ray, must determine to what extent reabsorption had taken place and whether it was time to make an injection of nitrogen. The following accident might occur: if a cavity of the lung extended well to the pleura the wall of this cavity might be injured during the process of separating adhesions. In that case the inspired air would gain access to the pleural cavity through the lung. If, then, owing to the valvelike action of the tear in the wall of the lung cavity, this air was prevented from returning through the bronchus as easily as it had entered, the pleural cavity would continue to fill with air until the intrapleural pressure forced it out between the two ribs that had been separated. In consequence a subcutaneous emphysema would result, the closure of the skin as a rule preventing the air from passing out. The probability also existed that the pleura would be infected from the lung cavity. It was evident that one should avoid this by proceeding with particular caution when separating the adhesions over the lung cavity, the site of which had been accurately located in advance. If one had reason to believe during the separation of the adhesions that the cavity had been perforated it should be sought by inflation and repaired. The writer said he had performed this operation on but one case, and reported it in order that those who had suitable clinical material at their disposal might make further study of the procedure. From the case reported the writer concluded that the operation itself was well borne by a very weak patient, declared by the visiting physicians in the hospital to be an absolutely hopeless case and near death. Secondly, there was the marked diminution of cough after the third day; thirdly, the drop to normal range of the temperature after the third week, and, fourthly, the disappearance of the cavity by *x*-ray picture, not to speak of the subjective improvement. Finally, the operation was easy of performance, the only point of importance in the technique being the avoidance of injuring the cavity. This operation was indicated in cases in which ordinary pneumothorax would be indicated and in cases of bronchiectasis.

Dr. Willy Meyer said that every contribution to the new field of thoracic surgery must be welcome. He therefore had listened with interest to Dr. Torek's remarks. He stated that within the last year pulmonary tuberculosis had clearly become a borderline disease. Cases, particularly those with cavity formation in the upper lobes of the lung, which latter was totally adherent to the chest wall, so that nitrogen insufflation had no effect upon the trouble and which no longer yielded to medical and hygienic treatment, were now referred to the surgeon. Otherwise utterly lost these patients could frequently be greatly improved or cured by operative collapse therapy. This could be done from without, above, or below. Thoroplasty, apicolysis, and unilaterally paralyzing the diaphragm by means of phrenectomy represented the means of attack. All these operations were done extrapleurally. The recently published statistics of Sauerbruch of Zürich, who it seemed had had the greatest number of operations for pulmonary tuberculosis, were extremely encouraging. In more than 100 cases he only had three deaths that could be attributed to the operation. The majority were cured and a great number much improved. The operation most frequently performed was multiple rib resection done under local and regionary anesthesia (thoracoplasty), which was often combined with pneumolysis and the introduction of a paraffin plomb, of late also with artificial paralyzing of one-half of the diaphragm. *X*-ray pictures after phrenicotomy showed that a paralyzed diaphragm rose up to the second or third rib, in this way greatly assisting in compressing the diseased lung. Dr. Meyer personally was in favor of working extrapleurally in these cases. So far he had done the operation only once, following Tuffier's plan of loosening the apex of the lung after resection of the second rib, and carefully making his way into the space between the costal pleura and the endothoracic fascia. The operation could be nicely done under local and regional anesthesia. It had been his intention to close the wound without the insertion of a plomb. However, a venous hemorrhage set in almost toward the end of the operation, most likely from the internal mammary vein or one of its branches, and gauze tamponade became necessary. Four days later a paraffin plomb was introduced, but had to be removed after four days on account of rising temperature. In the further course of the after-treatment a perforation of the pulmonary plus costal pleura occurred, evidently due to an involvement of the pleura in the tuberculous process. The patient, who had been brought on from a sanatorium by his physician, was asked to stay for further treatment, but decided to return to the sanatorium. As far as he could judge he thought there was still more tendency to perforation when the work was done within the pleura and entering the space between the pulmonary pleura of

the lobe which harbored the abscess cavity, and the costal pleura. In many instances these cavities were close to the surface; in many also the pleural cover was involved in the process. Manual perforation would be the threatening complication, no matter how gently separation had been done. An acute tuberculous pyopneumothorax would be the consequence, an extremely grave complication, and an occurrence which also happened in Dr. Torek's case. Dr. Meyer said that if he were to express an opinion at the present moment he would say that according to experience thus far gained extrapleural pneumolysis was less dangerous and therefore preferable to the intrapleural route.

A Case of Cervical Rib with Operation; Report of Five Other Cases.—Dr. HENRY LOWNDES LYNAH and Dr. LEON T. LEWALD presented this specimen, related the history of the case, and exhibited lantern slides of five other cases. Dr. LeWald stated that the specimen had been removed from a woman thirty years of age, who had suffered with cough, spasmodic dyspnea, and loss of voice. The patient was fairly well nourished and the family history was negative as regards tuberculosis or malignant disease. She had had all the diseases of childhood, with the exception of scarlet fever. The cough had been troublesome off and on for a period of about four years and was always aggravated by damp weather. There was no expectoration. The voice was lost at times for a few hours and at other times for ten or twelve days. The most prominent symptom was headache referred to the left side, from which the patient had suffered for about ten years. These headaches had been treated by many remedies, but with little relief. For the past four years the patient had observed loss of power in the left hand and arm and there were constant twinges of pain in the arm. A physical examination failed to reveal any abnormality of the antrum, nose, or pharynx. There were no lingual tonsils. The ventricular bands were normal; the vocal cords were slightly reddened; the arytenoid cartilages were not infiltrated. The left arytenoid did not pull as far apart as the right in abduction. There was no sign of dyspnœa. There was no enlargement of the thyroid, but there was an enlargement of the left supraclavicular fossa, which was firm to pressure and on deep palpation gave considerable pain. There was no tumor projection on the right side. There was no apparent atrophy of the muscles, but the patient's symptoms were undoubtedly due to pressure. A radiograph was taken, which showed that the patient had cervical ribs on both sides of the spine—the right a floating rib with no pressure symptoms, and the left firmly attached. An operation was performed on March 27, 1913. A vertical incision three inches in length was made behind the sternomastoid muscles, and blunt dissection down to the most prominent portion of the rib and then followed toward the spinal column. The great vessels and veins were protected as well as possible and were drawn aside by gentle traction. When the rib was denuded almost to its spine it was divided by a small pair of bone forceps. The rib was raised and dissected from its lower attachment and gently raised so that leverage made the dissection a bit easier. The dissection was carried down to the clavicular end, great care being taken to pull the great vessels out of the way. The articular surface was found to be on the second rib, the cervical rib being the first. This attachment was removed with great care, but the pleura was opened at this site. The rough edges remaining at the spinal attachment were removed with vonger forceps, and the wound closed, except at the lower angle, to allow for drainage. The patient had been free from headache since she came out of the anesthetic and had had no recurrence. Some paralysis followed in the ulnar and musculospiral nerves. These were troublesome, but after three months' treatment with Faradic and high-frequency currents there were no signs of trouble. The cough and husky voice had disappeared. As the patient was a resident of Kentucky it was impossible to present her, but Dr. LeWald said he had seen her five months ago and she was in perfect condition and had the free use of her hand. At times especially in changeable weather, she suffered from some pain in her shoulder. The muscular power of the left hand was as strong as that of the right. Keen and others who had operated on this condition knew that it was a most difficult task, but in certain cases the operation must be performed and the rib removed for the relief of pressure symptoms. Dr. LeWald had studied five other cases from the roentgenological standpoint. He had found that in the majority of cases there were only eleven other ribs. This suggested that the malformation was rather an abnormal development of the thoracic ribs without the addition of an extra rib. In the cases showing twelve ribs, in addition to the cervical one, the twelve ribs were rudimentary. The importance of this finding should be taken into consideration in operating on these cases, for the reflection of the pleura might be close to the cervical rib and injured in the removal of the rib unless extreme care be taken.

Demonstration of X-Ray Plates.—Dr. FISCHER said he would not go into details about the different radiological points that had been mentioned as of importance to distinguish a relaxation of the diaphragm from a diaphragmatic hernia. They were all more or less fallacious in a given case. In studying, however, all the available *x*-ray plates of hernia and relaxation he had come to the conclusion that the presence of an outspoken dextrocardia almost with certainty points to a relaxation of the diaphragm. A complete dextrocardia was never found in hernia of the diaphragm. It seemed to him, therefore, that a dextrocardia was the most important and the most easily demonstrated differential diagnostic point, between the two diseases.

Diaphragmatic Hernia Into the Right Thoracic Cavity.—Dr. M. S. KAKELS and Dr. SEYMOUR BASCH presented this specimen. They stated that true congenital diaphragmatic hernia of the stomach in an adult was comparatively rare, and a diaphragmatic hernia of the stomach in an adult into the right thoracic cavity was very unusual. So far as they had been able to ascertain they believed this specimen to be unique. That it was a true hernia was evidenced from the fact that the hernia had a distinct sac made up of peritoneum and parietal pleura. There were certain regions of the diaphragm where hernia was more apt to occur than at others. These were Larry's space or foramen Morgani, the foramen Bochdaleki, the opening through which the sympathetic nerve passed, and sometimes at the hiatus esophagus. Some of these areas between the muscular portions of the diaphragm were filled in only with areolar tissue and covered only by peritoneum and pleura so that at these gaps the abdominal and thoracic cavities were only separated by a thin layer of connective tissue. Embryologically, the posterior portion was the last to form and in this fact was probably to be found an explanation why congenital diaphragmatic herniæ were more usually found in the posterior half of the diaphragm between the *pars vertebralis* and the *pars costalis*. The specimen which was shown was at this site. The patient was referred to the speaker by Dr. Basch for an exploratory laparotomy for peculiar gastric disturbances.

The patient was 54 years of age. His family history was negative and he had led a regular life avoiding strains on account of an inguinal hernia. Two years ago he experienced pain across the upper abdomen which gradually increased in severity. There was no nausea, vomiting or dyspnea. The pain became aggravated, his hands were cold and face was drawn. A physician was called who administered a hypodermic of morphine which relieved his symptoms. The following day he remained in bed and another physician found his abdomen much distended. He resumed business on the following day. For four or five weeks he occasionally experienced these sharp pains across the epigastrium. About the beginning of December, 1913, he had a similar but milder attack. He continued to have these attacks, beginning late in the afternoon, and getting more severe. They were relieved only by repeated forced vomiting, at first only a little phlegm, but later amounts of sour-tasting and yellowish fluid sometimes as much as two quarts, but never containing any food. These attacks had occurred at first about every two months, but for the past two or three months about once a week. He had lost 35 pounds, and strength was much diminished. On February 26, 1914, an exploratory operation was performed. A greatly distended transverse colon was found covered with enlarged vessels and occupying the region of the stomach. On pulling this out of the way, the gastrocolic omentum was pulled down and the pyloric end of the stomach was all that was seen emerging from an opening high up in the diaphragm on the left side, behind the liver near the left crus, between the *pars vertebralis* and *pars costalis*. The rest of the stomach with the whole of the great omentum was in the thoracic cavity outside of and behind the pericardium. After withdrawing the omentum and the enormously enlarged stomach, the hand was introduced into the opening which was found

to extend upward and inward into the right thoracic cavity through the posterior mediastinum. The heart could be distinctly felt in front of the cavity. The stomach resembled the hour-glass stomach and had to be pulled from the thorax with considerable force and when released receded to its abnormal position. The reduction of the hernia because of the negative pressure above the diaphragm, was unsuccessful. The dome of the diaphragm was so high that no attempt at suturing the stomach to the margins of the opening was made; furthermore the condition of the patient did not permit of extensive operative procedures, such as resection of the ribs and approaching the hernia from the thoracic side. The abdomen was closed. The radical cure of this large hernia seemed hopeless. The patient died thirty-six hours later. At autopsy no pleurisy, pneumonia or peritonitis was found. The sac containing the stomach and the great omentum was found in the right thoracic cavity reaching as high as the second rib. The hernial sac was made up of the peritoneum lining the under surface of the liver, and the parietal pleura of the thoracic cavity. It seemed that the hernia was produced gradually by the stomach forcing its way through a weak place in the diaphragm. There was no history of severe trauma in which the existence of rupture of the diaphragm could be suspected. The history and symptoms were those of indefinite gastric complaints without dyspnea, rather unusual in the face of such a grave condition.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

PSYCHOPATHOLOGY OF EVERY DAY LIFE. By Drs. FREUD and BRILL. Cloth; published by The Macmillan Company; price, $3.50 net; 338 pages.

FEEBLE-MINDEDNESS. By Dr. HENRY HERBERT GODDARD. Cloth; illustrated; published by The Macmillan Company; price, $4.00 net; 590 pages.

TWENTY-FIFTH REPORT OF THE SUPERINTENDENT OF THE JOHNS HOPKINS HOSPITAL. Paper; illustrated; 140 pages; published by the Johns Hopkins Press.

DISEASES OF THROAT, NOSE, AND EARS. By W. L. BALLENGER, M.D. Cloth; illustrated; fourth edition; 1,080 pages; published by Lea & Febiger.

MENTAL DISEASE AND DEFECT IN THE UNITED STATES TROOPS. By Capt. EDGAR KING. Paper; 204 pages; Washington Printing Office.

BLOOD PRESSURE: ITS CLINICAL APPLICATION. By G. W. NORRIS, M.D. Cloth; illustrated; 372 pages; published by Lea & Febiger.

RECREATIONS OF A PHYSICIAN. By A. S. M. CHISHOLM, M.D. Cloth; 328 pages; published by G. P. Putnam's Sons; $2.00 net.

FOOD IN HEALTH AND DISEASE. By WILLIAM TIBBLES, M.D. Cloth; 628 pages; published by Lea & Febiger.

EXPERIMENTS. By PHILIP E. EDELMAN. Cloth; illustrated; 236 pages; price $1.50. Published by Philip E. Edelman, Minneapolis.

CHEMISTRY FOR NURSES. By REUBEN OTTENBERG, M.D. Cloth; 141 pages; price $1.00. Published by the Macmillan Co.

INTERNATIONAL CLINICS. By leading members of the medical profession throughout the world. Cloth; Vol. III, twenty-fourth series; 309 pages. Published by J. B. Lippincott Company.

DISEASES OF THE NOSE AND THROAT. By WRIGHT & SMITH, M.D. Cloth; illustrated; 683 pages. Published by Lea & Febiger.

MANUAL OF OBSTETRICS. By EDWARD P. DAVIS, M.D. Cloth; illustrated; 463 pages; price $2.25 net. Published by W. B. Saunders & Co.

A MANUAL OF NORMAL HISTOLOGY AND ORGANOGRAPHY. By CHAS. HILL, M.D. Cloth; illustrated; third edition; 483 pages; price $2.25 net. Published by W. B. Saunders Co.

DISEASES OF THE SKIN. By Dr. KNOWLES. Cloth; illustrated; 546 pages. Published by Lea & Febiger.

THIRTY-SEVENTH REPORT OF THE STATE BOARD OF HEALTH OF NEW JERSEY. Cloth; 831 pages.

Therapeutic Hints.

Prescriptions for Skin Diseases of Children.—Goodhart and Still use the following as routine formulæ for ointments in the treatment of cutaneous diseases in children:

For eczema:

℞ Resorcin, gr. xxxv
Zinc oxide, gr. xxxv
Subnitrate of bismuth, gr. xxxv
Birch tar, gr. xxxv
White wax, gr. lxxx
Soft paraffin, ℥ss
Hydrous wool fat, ℥ss

For ringworm:

℞ Ammoniated mercury, gr. vj
Red oxide of mercury, gr. vj
Essential oil of almonds, ♏ij
Benzoinated lard, ℥j

For scabies:

℞ Sulphur, ℥ss
Ammoniated mercury, gr. iv
Creosote, ♏iv
Oil of chamomile, ♏x
Lard, ℥j

—"Diseases of Children."

The Phenol-Serum Treatment of Pyogenic Processes.—O. Geiger cites the pioneer labors along this line of A. Lorey and B. Küstner. His material consisted of three cases of inflammation and abscess formation of the parametrium, one case of peritoneal abscess, one case of abscess of the abdominal wall, and one case of infected superficial wound. The technique of the treatment was as follows: Three hundred cubic centimeters of serum obtained from one liter of fresh horse's blood was diluted ten times with physiological salt solution and then admixed with phenol to the extent of .5 per cent. of the latter. The phenol-serum mixture was applied locally in the different cases, abscess cavities after evacuation being filled with the serum, or packed with tampons saturated with the latter. The results were invariably a rapid demarcation of the necrotic tissues and a prompt cleaning of the infected region, such changes as have not been observed by the author following as quickly any other method of treatment in similar cases. The explanation of the happy result of this method is a biochemical one. The albuminous substances in the serum in loose combination with the phenol, by virtue of the greater dissolving action on the lipoids thus exerted by this combination inhibits the development of the infecting bacteria, while at the same time no deleterious influence is exerted upon the tissues of the wound or infected region.—*Beiträge zur Klinik der Infektionskrankheiten und zur Immunitätsforschung.*

Serum Treatment of Vomiting of Pregnancy.—T. Spies has essayed this method of treatment with great success in one case of severe vomiting of pregnancy. Le Lorier in 1911 was the first to report the happy effects following the use of horse serum in the incoercible vomiting of pregnancy. In the same year Freud had recommended the use of horse serum in the treatment of the dermatoses, and Mayer had demonstrated the advantage of the use of blood serum obtained from a pregnant woman in the treatment of persistent vomiting in another pregnant woman. Spies injected into his patient two doses of 10 c.c. each of horse serum, at an interval of three days. The vomiting was fully controlled after the second injection.—*La Clinique.*

THE MEANS BY WHICH INFECTIOUS DISEASES ARE TRANSMITTED AND DISINFECTION.

BY ALVAH H. DOTY, M.D.,
NEW YORK.

No subject relating to the prevention of infectious disease has been more generally or more vigorously discussed than Disinfection. This is largely due to the fact that a wide diversity of opinion exists concerning this form of protection, for theoretical conclusions have been so confused with the data presented by practical sanitarians that it is difficult for those not personally familiar with this subject to decide under what conditions germicidal agents should be employed as a preventive measure.

In order to obtain a clearer understanding of this subject we must consider not only the various means which have been employed from very early times to the present day in guarding against infectious diseases, but also the theories concerning the manner in which they are transmitted.

Although the term "disinfection" does not appear in connection with the descriptions of the early protective measures, the latter were nevertheless used for the same purpose, *i.e.* to destroy media of infection. During this period there was but little done in the treatment of articles believed to be contaminated which was not farcical or useless; such as incantations, sprinkling presumably dangerous articles or material with the juice of herbs, the burning of so-called magic powders as well as other substances, the offensive ones being regarded as the most potent for this purpose. The burning of sulphur as a protective measure became very popular and may be regarded as the connecting link between the past and the present so far as disinfection is concerned, for it has many advocates at the present time.

The early theories regarding media of infection were naturally founded on the scantiest reliable knowledge, but such as it was it gradually crystallized into what is now known as the "fomites" theory, which holds that infectious diseases are transmitted by various articles or material capable of conveying some active form of infection from one person to another. It will thus be seen that this belief was dominant long before any scientific or definite information was available; therefore it was born in ignorance and I may add has thrived upon it ever since.

The publication of the researches of Pasteur and Koch about 1880 was followed by the most energetic and exhaustive bacteriological investigation throughout the world and one pathogenic organism after another was identified, and it was only needed to determine some way by which these germs could be readily transmitted to satisfactorily explain the sources of infection. The fomites theory, although somewhat aged and worn, was prepared to assume this responsibility, and it was accepted without reserve, for there were but few articles which were not regarded as capable of transmitting infectious diseases from one person to another. The extent to which this was carried is probably known only to those who worked in the field—it is sufficient to say that it reached a point beyond all reason; even iron rails were disinfected to prevent the transmission of yellow fever. Gradually practical sanitarians were able to overcome this rather hysterical condition and a more rational era was established and the true means by which infectious diseases are transmitted were carefully sought for. The result has fully equaled the expectations of those who have been personally and practically interested in this investigation, for we are now in possession of indisputable evidence that many of our former theories regarding sources of infection are erroneous; at least sufficient knowledge in this direction has been secured to justify a most careful consideration of this subject with the view of making such changes as are necessary in our methods of protection against infectious disease.

In the consideration of this matter it is very important that we should carefully analyze the proof for and against the fomites theory, for it is chiefly upon the result of this that we must decide as to the extent to which disinfection is required.

I believe the most important testimony in connection with this subject is the personal experience of practical sanitarians rather than theoretical deductions. I can say very frankly that at first I believed with others that there was sufficient reliable evidence to support the fomites theory, but as my knowledge of infectious diseases has extended, proof of the fallacy of this theory has steadily increased. I am quite sure that this conclusion is shared by others who have had long practical experience in this direction.

It may very properly be asked on what grounds have I based by conclusions; my answer is, my own personal experience, the personal experience of others, and a careful and extended investigation of the subject. In this article I shall refer largely to evidence obtained in connection with my personal experience.

As clothing, rags, and money are regarded as among the most common media of infection, I will refer separately to some instances in connection with the investigation of these articles, the results of which are in harmony with many other researches in this direction.

As an illustration I may say that I witnessed in some of the great storehouses in Alexandria, Egypt, many women and children seated at the base of immense piles of rags which they were sorting over and separating for various commercial purposes. These rags which were really the cast

off clothing of the natives, came largely from the interior of the country where some form of infectious disease almost always exists, yet among the carefully prepared statistics of the British sanitary officers in charge I was unable to find the least evidence that these employees contracted disease through the medium of the rags they were constantly handling; this evidence tallied in every way with results obtained by a similar investigation previously made in this city, at which time rag sorting was a very active and somewhat important business, the work being carried out in close and badly ventilated cellars, yet no reasonable evidence could be obtained, although carefully sought for, that rags constitute a source of infection.

About this same period there existed in New York City many second hand clothing stores which were practically unmolested by the Department of Health. These stores usually occupied the front part of the ground floor of various buildings, the rear being used as living apartments by the proprietor and his family. Second hand clothing of every description, generally of the poorest quality and in the condition in which it was obtained from the owner, and without disinfection, was offered for sale. The members of the proprietor's family, both adults and children, were in the store a greater part of the time, yet a painstaking investigation covering a long period failed to reveal any evidence that infectious diseases were transmitted in this way.

Neither have I been able to obtain proof that bank tellers, cashiers of stores, restaurants, or other places where money is being constantly handled, contract infectious diseases through this source, although it is believed to be a most frequent means of infection. The most convincing proof which came under my observation relates to that part of the work of the Treasury Department at Washington which at the time of my investigation, ten or twelve years ago, dealt with the constant handling of an enormous amount of old and filthy money prior to destruction; even under these extreme conditions no proof existed that diseases are transmitted by this article, yet the statement that a bank clerk, cashier of a store or restaurant, or some one who is constantly handling money has contracted an infectious disease is sufficient evidence to satisfy a community as to the source of infection.

Curiously enough it is seldom considered that those who are constantly handling money or rags or other articles believed to be common media of infection, are fully as liable to contract infectious diseases in the same way that others do, for they visit, ride in public conveyances and attend public assemblages, therefore the fact that they sometimes have infectious disease is neither scientific nor reasonable evidence that infection is transmitted by the articles referred to. The only proper and logical proof of this would be the presentation of evidence that those who constantly handle money, rags, etc., are *more frequently* infected than those engaged in other work. No such proof has been presented nor will it be presented.

During the Spanish-American war it was believed that soldiers returning from Cuba transmitted the infection of yellow fever through the medium of their clothing, and instances were cited where these articles were responsible for various outbreaks of this disease, yet two or three years afterwards the medical commission appointed by the United States Government under the direction of Dr. Walter Reed presented conclusive evidence that yellow fever is transmitted only by the mosquito, and that clothing or other articles take no part in the transmission of infection.

Of all diseases typhus fever has been regarded as probably the most commonly transmitted by fomites; this is so stated in almost all of the text books. An unusual opportunity was presented to investigate the truth of this during the outbreak of this disease in New York City during 1892-3, at which period over seven hundred cases were discovered. These were dealt with by a large number of Department of Health officials who were daily in close proximity to the patients. These men were required to wear no gowns and went freely to and from their homes and the patients, yet in no instance did they transmit infection to their families or friends or so far as it could be ascertained, to anyone else. This is now easily explained for we have learned that typhus fever is not transmitted by fomites, but by the body louse, and furthermore these insects prefer not to leave those who are unclean, for during the outbreak referred to only two or three of the seven hundred cases occurred in the better walks of life, a very large percentage being traced to the cheap lodging houses in the Bowery. It may also be stated that the Department of Health officials referred to, who for years had been dealing with various forms of infectious disease, knew of no instances where there was reason to believe they had transmitted infection to their families or others, although they wore no gowns in their daily official examinations throughout the city.

It has also been shown that fomites do not transmit plague, although this disease was formerly believed to be conveyed from one person to another in this way, for instance through the medium of infected rugs and other material brought from the East, largely by caravans and other means of transportation. I visited Russia some years ago during an outbreak of plague, and found that fomites were regarded as a common source of infection and largely responsible for the frequent outbreaks that occurred in that country. Now it is generally accepted that this disease is transmitted by the flea which infests the rat and also by the infected discharges of those who are suffering from this malady, and not by clothing or other things.

It is true that so far as measles, scarlet fever, diphtheria, smallpox, and chickenpox are concerned no such definite proof exists as to the fallacy of the fomites theory as has been presented in connection with the group of diseases just discussed, yet there are the best reasons to believe that these diseases are also not transmitted by fomites. Evidence of this has come to us from various reliable sources; for instance, it has many times been shown that where outbreaks of these diseases have occurred and have been attributed to infected clothing, etc., they were really due to mild ambulant or unrecognized cases or carriers, which constitute the most dangerous media of infection, for unnoticed and uncared for they are constantly transmitting disease.

Further proof that they are not transmitted by clothing, money, rags, etc., is found in the report of the various School Corps which in recent years have been organized by the Departments of Health in many large cities. These corps are composed of medical inspectors who daily, or at short intervals, examine public school children. Their reports are

extremely interesting, for they clearly show that the increased number of cases of measles, scarlet fever, and diphtheria found among children at the beginning of the school year is not as it was formerly believed, due largely to the infected clothing of children in whose home some form of infectious disease existed, but rather to the presence of actual cases in the school, although in a mild or unrecognized form. These reports have very well demonstrated that what are supposed to be common colds are often found to be mild cases of measles, and apparently an ordinary case of sore throat is often found to be scarlet fever or diphtheria in a mild form. It is fair to assume that under former conditions these cases would not have been recognized.

So far as smallpox is concerned, I may say that each year of my experience with this disease has furnished additional proof that it is not transmitted by fomites.

Reference may be made at this point to the alleged danger of the "desquamation" of measles and scarlet fever as a medium of infection. While this theory is very generally accepted, I believe there is no real scientific or definite evidence that infection is ever transmitted in this way, furthermore the alleged proof of this comes to us largely from the laity, and the busy practitioner has but little time to carefully inquire into the veracity of these stories. I have investigated many of them and have yet to find any reliable evidence that measles and scarlet fever are transmitted through this source, although the theory furnishes a plausible explanation for outbreaks of these diseases, the true origin of which is unknown. I believe that measles and scarlet fever are not only not transmitted by desquamation, but that this belief has been responsible for the extension of these diseases, for children are often released from quarantine at the termination of desquamation, yet with active discharges from the infected membranes. *It is the latter which constitute the true media of infection.*

The aerial theory of infection has also led to many extravagant statements concerning the transmission of infectious disease through the air pertaining largely to the distances which infection may be conveyed in this way, even to the extent of a mile or more; notwithstanding much theoretical evidence to the contrary, I am quite sure there is no practical or scientific proof to support this belief. I have no respect for the theory beyond the fact that infection takes place through the air in close proximity to the patient; besides it is one of the theories which are constantly distracting our attention from the true sources of infection.

It is exceedingly difficult for those who have not had long practical experience with infectious diseases nor have carefully investigated the origin of outbreaks as well as secondary cases, to abandon the fomites, aerial, and desquamation theories, which have so long performed their purpose, for they are plausible and apparently so clearly explain outbreaks of infectious diseases, particularly in isolated places where apparently there are no other possible means of infection, that it seems foolish to look for any further explanation. I am quite sure that those who argue this way have not been impressed by actual experience with the frequency with which mild and unrecognized cases and carriers occur—the ordinary investigation usually stops short of securing satisfactory evidence to this effect.

I believe there is nothing connected with this subject which is so important and which so clearly indicates the great strides which have been made in the protection of the public health against infectious diseases, as the conviction on the part of health officials that success in dealing with outbreaks of these diseases depends chiefly upon exhaustive investigation to ascertain the real cause by which they are transmitted from one person to another.

It is very easy and convenient to accept the belief that germs in their active state are present in the apartment of those sick with infectious disease, and ready at any moment to seize upon a victim, and that protection against this condition is secured chiefly by what is known as terminal disinfection, which refers to the use of germicidal agents in the apartment upon the termination of the case.

It is possible that pathogenic organisms may be found in the sick room and elsewhere; however these are much less in number than it is commonly believed; besides being removed from proper media they are disabled, and in this condition of little danger and can be effectively dealt with by fresh air, sunlight, and cleanliness; besides it is very important to remember that modern sanitation does not guarantee complete safety particularly in connection with preventive measures and attempts to secure this by undue consideration of improbable media of infection often defeats the end in view.

The public is constantly harassed by the fear that infection lurks everywhere, in public conveyances, public assemblages, clothing, money, rags, books, carstraps, etc., and that diseases are commonly conveyed by these means. This is not true except possibly in some rare or unusual instance, and if disease is transmitted in a public conveyance or assemblage it is through the medium of some infected person present and not from the interior of these places or their equipment. For instance we may be in close proximity to a case of smallpox and in this way contract the disease, but I do not believe we will transmit it to our family or others through the medium of our clothing as it is commonly supposed.

The public should know that diseases are transmitted by persons and not things. Such teaching not only does not encourage carelessness but adds greatly to the protection of the public, for it emphasizes the importance of securing prompt medical attention when illness occurs in order that infectious disease may be quickly identified and the necessary precautions taken to prevent its extension.

There is probably nothing more impractical or unjustifiable than an attempt to disinfect money; in the first place there is no necessity for this action and if it were required it could not be effectively or practically carried out. Money is distributed everywhere and it may very pertinently be asked, where and by whom would it be disinfected, what method or treatment would be employed and how often would it be required? The latter is an important consideration; for money after disinfection would be returned at once to the general circulation and the collection of germs would begin again. Furthermore, the germs found on money, with but few exceptions, are harmless ones.

There is an occasional revival of the scare re-

garding the danger of transmitting disease by books; this is also without justification; besides it is very unfortunate for it is a source of considerable worry to those whose chief pleasure consists in reading and who may for a large part of the time be found in public libraries. Practically infection is not transmitted by books although the latter are not infrequently claimed as a source of infection to explain outbreaks of infectious disease the origin of which is not known or has not been carefully investigated. As with money, books could be effectively treated only with steam, notwithstanding statements to the contrary, and this agent would be sure to injure or destroy them, particularly those which are bound with stiff covers. Those who suggest this unnecessary procedure have but little conception as to what it would involve if it were logically carried out, for as books in public libraries are undoubtedly oftentimes read by those having mild and unrecognized cases of infectious diseases it would follow that if there was real danger from this source, books in all public libraries would require some form of treatment. It would be well for those who advocate action in this direction to consider, for instance, the approximate time and labor which would be required in the disinfection of books in the great public libraries of New York, and then to bear in mind that the same theory which calls for the disinfection of books would also call for their redisinfection for germs would, presumably, accumulate as soon as the books were replaced upon the shelves for general distribution.

A large amount of literature has been presented regarding the danger of contracting disease in cars, particularly sleepers, and much money is constantly being spent for the disinfection of these vehicles, yet but little is written or said regarding the danger of possible infection in theaters and other public assembling places where the ventilation is rarely good and where the sunlight never enters and but little attempt is made to properly remove the accumulation of dirt and decomposed matter which is constantly collecting in these places. On the other hand, it is almost impossible to prevent the frequent entrance of fresh air into cars; besides they are flooded with sunlight.

If cars are frequently and thoroughly cleaned with soap and water, for there is nothing else which so effectively removes dirt and greasy matter, and special attention is given the toilets and the drinking water supply, and individual cups are provided, and if the linen used in sleeping car berths is removed each morning and boiled as promptly as possible upon reaching a central station, and fresh linen is used whenever a berth is made up, nothing further is called for so far as complying with reasonable and practical sanitary measures is concerned.

Frequent allusion is made to the alleged danger of the blankets used in the make up of the sleeping car berths; there is no objection to the occasional disinfection of these articles, but why should they be singled out for special treatment in this direction when practically no attention is given to the supervision of bed and bedroom equipment of other public places where many of the rooms have little or no ventilation or sunlight, with questionable bed equipment, these are probably oftener occupied by tuberculous cases than sleeping cars are and less care is observed in expectorating about the place.

It is true that the present method of admitting air into the individual sleeping car berths is primitive and unsatisfactory but while it is unpleasant and a great discomfort, it does not really affect a person's health, for nature is very tolerant of these transient conditions. I do not digress from the subject of this article to speak at length of car sanitation in extenuation of what may be uncomfortable in the arrangements of these vehicles, but there are so many really bad and unsanitary permanent conditions to which the public is subjected, it seems only proper that we should bend our energies towards relieving these rather than to give undue time and attention to matters which involve personal discomfort rather than impairment of health.

The value of strict cleanliness refers equally to the school house and the workshop, and if this is faithfully carried out there is, under ordinary conditions, no need for disinfection.

I do not believe that any reliable proof has ever been produced to show that baggage or cargoes of vessels transmit infection, yet commerce and shipping throughout the world are being constantly annoyed and subjected to great expense and delay by regulations relating largely to disinfection enforced for the purpose of protecting against fomites.

There is no one practically familiar with this subject who does not consider that in some unusual or rare instances infection may be transmitted by clothing, money, or some other article, but this is so uncommon that it is a negligible factor, and we need not attempt to deal with it, but should turn our attention to the common media of infection which will fully occupy our time and which if properly dealt with will surely lead to successful results in the protection of the public health.

Granting, for the sake of argument, that diseases are transmitted by fomites and that there is danger in the apartment where a case of infectious disease has been cared for, then there is good reason to believe that the methods of disinfection hitherto employed have been of little or no value as means of protection.

After three years of careful investigation and experimental work with sulphur dioxide and formaldehyde gas, I found that these agents which in the past have been relied upon for room disinfection were practically worthless, so far as penetration is concerned and that sulphur dioxide cannot be depended upon even for superficial disinfection unless a certain amount of moisture is present. If the air was not sufficiently humid during the experiments referred to, artificial moisture was supplied, yet under these conditions satisfactory results were not always obtained. If with these precautions disinfection was not uniformly successful, how can good results always be expected in connection with the methods of disinfection usually employed, *i.e.* without any attention paid to the presence of moisture, often without proper combustion of the sulphur and with the apartments insufficiently sealed?

The experiments to which I refer did not show that formaldehyde gas possessed any special advantage over sulphur dioxide, so far as room disinfection is concerned, except that moisture is not required and that this gas does not tarnish or otherwise injure the contents of the apartment. It must be borne in mind that in the employment of gaseous or superficial disinfectants the material to be treated is not often carefully spread out with all

surfaces exposed, but is commonly folded or one article placed upon another. Therefore, from a practical standpoint, even reliable superficial disinfectants cannot always be depended upon.

I believe that the protection claimed for room disinfection under any form of treatment, gaseous or otherwise, is questionable, and that secondary cases have not followed as the result of this method, but rather because there is little or no danger from this source.

The very important question naturally arises: if infection is transmitted only in rare instances by fomites and not over long distances through the air, what, then, are the real or common means by which diseases are conveyed from one person to another? I believe we are in possession of sufficient indisputable evidence to satisfactorily answer this question.

We have learned that infectious diseases are transmitted by discharges directly from one person to another by contact; by food and drink, or articles about the patient, or through a very limited space, rather than by such things as clothing, money, etc. In other words, by persons and not things. We know that infectious diseases are also transmitted from one person to another by insects. During the past few years, more than ever before, we have appreciated the frequency with which diseases are conveyed by mild, ambulant, irregular, and unrecognized cases and carriers. The fact that these very common media of infection have not until recently been given proper consideration goes far to account for the popularity of the fomites theory.

Success in the prevention of infectious diseases depends upon the early detection of the case, proper isolation of the patient and the prompt disinfection or destruction of infected discharges and strict cleanliness. In addition, protection must be afforded against certain insects which transmit infectious diseases. Cleanliness in dealing with infectious skin diseases by the frequent removal and destruction or disinfection of the coverings of the body is in line with this protective measure and will go far to diminish the danger from this source.

The detection of infectious disease becomes far easier if we abandon the fomites theory, for then we know that if a case of this kind occurs and no previous one of the same character has been reported, we cannot assume that the disease was contracted through the medium of clothing or some other article, but by a previous case, and that a most exhaustive examination must be made to discover the person or persons affected. This will often take some time, and is more or less trying to the patience of a health official, but it is quite sure to be followed by success. The source of infection will often prove to be a mild, unrecognized case or a carrier.

The most important detail in connection with the care of the patient relates to the prompt destruction or disinfection of the infected discharges as well as the material and articles used about the patient. To this must be added constant cleanliness which means the free use of soap and water. I am aware that soap cannot be depended upon to disinfect; on the other hand, soap and water does not constitute a very healthy medium for the growth of organisms, besides discharges, are viscid and sticky and not readily penetrated by the various disinfecting solutions, although they are promptly released and removed by soap and water.

In connection with this part of the subject I may say that I have had, under my direction, children affected with measles, scarlet fever, and diphtheria, who were treated under the same roof, with only dwarf partitions between the various groups of these diseases, and all under the care of the same nurses who went freely from one ward to another with practically no change of clothing, yet there was no evidence that any interchange of infection occurred. In this service strict cleanliness was demanded, the discharges were promptly removed and immediately destroyed and the skin and affected passages kept carefully cleaned. Rubber gloves were used by the nurses while removing the discharges from the patients, the gloves were then boiled and the hands again carefully washed. It would seem that the result obtained in this way goes far to confirm the belief that infectious diseases are transmitted directly by discharges rather than by fomites or aerial disinfection.

There is probably no form of disinfection which has less practical value than that usually employed in connection with the treatment of the stools of typhoid fever patients. The ordinary method consists in placing a solution of carbolic acid or some other disinfecting agent in the bed pan, the stools being received in this solution and allowed to stand for various periods, the receptacle then being emptied in the water closet or privy vault. This does not properly disinfect the stools, besides it leaves an infected receptacle which is not often properly treated and is unquestionably a source of danger.

Some time ago I carried out a series of experiments relating to the disinfection of fecal matter which consisted in placing this material in the various disinfecting solutions commonly employed for this purpose in private and hospital practice. It was found that it required at least twenty hours to disinfect only the outer part of the mass. These results were confirmed by many similar experiments.

The ordinary treatment of the stools of typhoid fever patients is probably no less valuable than the means usually employed in the sick room to disinfect the hands. This is commonly done mechanically and consists in dipping the hands for a moment or so in a solution of carbolic acid, bichloride of mercury or some other germicidal agent without the previous use of soap and water, whereas it has been found that an immersion of at least a minute is required for disinfection under these circumstances; the viscidity of the discharges must be taken into consideration; it is the removal as well as the destruction of this matter which is called for, and it is for this reason that soap and water is an equally valuable preventive measure.

It is not my purpose in this article to discuss the relative value of the various germicidal agents beyond the statement that there is no disinfectant as valuable as boiling water or steam. They act surely and quickly; boiling water is not dangerous, costs nothing and is always available. I am quite sure that in the future the importance of heat for practical disinfection must be more fully appreciated. Boiling water is best adapted for the sick room, for an electric, gas, or oil stove and a receptacle for holding water may be obtained almost anywhere and at a comparatively small price, and this apparatus may be placed in the sick room or one adjoining it and used for the disinfection of all infected material and articles connected with

the patient. The receptacle should be large enough to admit a bed pan in order that the latter, as well as the stool, may be disinfected at the same time, a very important consideration, for handling the bed pan after the discharge has been removed for the purpose of cleaning or disinfecting it is undoubtedly a source of infection.

A very effective and inexpensive apparatus for disinfection with boiling water in or near the sick room may be constructed of sheet copper, sufficiently large to hold a full-sized bed pan, having some form of metal support to raise it sufficiently high to admit underneath a lamp or gas apparatus for generating heat. The cover of this apparatus should be heavy enough to offset a slight pressure of steam; this, however, is still better provided for by a spout which is attached to the portion of the top of the apparatus not involved in the cover or lid; to the upper part of the spout may be attached a flexible tube extending outside of the window in order that the steam may escape. If any odor exists it may be neutralized by a small amount of permanganate of potassium, or some lime thrown in the water. A large apparatus constructed along these lines with accommodation for eight or ten bed pans was employed for the disinfection of the discharges of cholera patients at Swinburne Island Hospital in 1909-10, with the best results. However, a steam chamber or apparatus is far more convenient and effective for this purpose than boiling water where large numbers are concerned, and should form a part of the equipment of every hospital.

We have been under the influence of some erroneous theories regarding the means by which infectious diseases are conveyed from one person to another; this has led to the employment of various measures which are not only unnecessary, but which have gone far to discourage extended investigation to discover the true media of infection. We have been guided largely by the fomites theory and have assumed that diseases are commonly transmitted by apartments, clothing, and innumerable other articles, which is untrue. Under these conditions it is very easy for a public health official when an outbreak of infectious disease occurs to assume, if its origin is in doubt, that the disease was probably introduced into the community by infected clothing or some other article, yet it is far better for the health of the public that he should disregard the fomites theory and maintain that the disease was contracted from another person and leave no stone unturned until the case is found. I believe that such a policy strictly adhered to is the most important factor in the prevention of infectious disease, for it brings under isolation and observation mild and unrecognized cases and carriers which otherwise would have continued to act as media of infection and which incidentally furnishes support to the fomites theory. When to this is added the prompt destruction or disinfection of the discharges and the material and articles used about the patient and the observance of strict cleanliness we need not be concerned about the alleged danger of transmitting infection through the medium of rooms, clothing, money, books, and other articles which are commonly looked upon as a menace to health.

Assuming that in some unusual instances disease may be transmitted by fomites, we must remember that there are no sane means by which absolute safety can be assured, therefore our efforts should be to secure the greatest protection through measures which are reasonable and practical. I believe this is modern sanitation. There are many members of the medical fraternity who are working along these lines, but the initiative in this important advance must come from public health authorities, for it would not be consistent or politic for physicians in private practice to abandon room disinfection or the use of germicidal agents in other directions, unless such action has not only the approval but the cooperation of health officials. In some sections of the United States this has already taken place with the most satisfactory results.

It is proper that we should proceed carefully, but it is necessary that we should make a beginning, otherwise no progress will be made in this direction. I believe it is entirely justifiable without further evidence to abandon room disinfection in the case of diphtheria, measles, and scarlet fever and recognize that it is the discharges in these diseases that constitute the media of infection and which call for the most prompt and careful attention; in the past, so far as prevention is concerned, we have rather worked on the wrong end of infectious disease, for as a preventive measure the destruction of the discharges and constant cleanliness have been subservient to terminal or room disinfection, which is of very doubtful value.

Having made this start it will be far easier to decide what action shall be taken concerning other details of this subject.

It is unnecessary to refer to the importance of disinfection in connection with the treatment of infected discharges and care of the patient under the direction of a physician, but beyond this the practical value of germicidal agents is entirely overestimated, yet they are purchased and commonly and indiscriminately used by the public as a "cure all" under the impression that extended protection is guaranteed through this source which is not true; besides this belief goes far to mask the inestimable value of cleanliness.

It is very easy to distribute a disinfectant about the premises believing that all germs have been destroyed and no further action is necessary. This is not modern sanitation, for it is required that dirt and filth shall be removed and not treated. This applies equally to the ice box, kitchen, workshop, school, or public conveyance, and can be properly accomplished only by the free and constant use of soap and water and scrubbing the nooks and corners; besides this method teaches the public that cleanliness is an exceedingly important sanitary measure, which, if properly carried out, goes far to aid public health officials in the prevention of disease.

205 West Fifty-seventh Street.

CHRONIC MUCOUS AND MEMBRANOUS COLITIS.

A NEW METHOD OF TREATMENT.

By G. MILTON LINTHICUM, A.B., A.M., M. D.

BALTIMORE, MD.

FORMER PRESIDENT OF THE MEDICAL CHIRURGICAL FACULTY; PROFESSOR OF PROCTOLOGY, UNIVERSITY OF MARYLAND; PROCTOLOGIST, MARYLAND GENERAL HOSPITAL AND UNIVERSITY HOSPITAL; STAFF, CHURCH HOME AND INFIRMARY.

In considering the treatment of this disease, the first question which presents itself must necessarily be one of its etiology, and at the same time its relationship to catarrhs of the colon. Literature upon this subject gives markedly different opinions ex-

pressed by equally eminent authorities. A good résumé is given by Nothnagel of the various authorities and their views upon this subject as to its cause. In considering it he discusses catarrh as a distinct and separate disease from mucous or membranous colitis, regarding the former as an inflammatory disease and the latter as being, in a majority of cases, purely neurotic in origin. In his discussion in the cause of mucous colitis he divides it into three distinct classes, according to their origin, grouping the first under the title given it by Ewald as a myxoneurosis; this is entirely neurotic in origin. A second group is neurotic in origin, associated with anatomical changes of the mucosa. In the third group are those derived from catarrhal conditions where the anatomical changes are predominant and not associated with the neurosis; these are entitled enteritis membranacea, this last being practically the same as a catarrhal enteritis, but associated with a formation of the mucous membranes or casts as one of its symptoms. The only apparent difference between this condition and chronic catarrhal colitis is that of the presence of mucus in the form of membranes or casts, whereas in the latter the mucus may be in small quantities and not definitely organized.

It is not my desire to laden these remarks with authorities to prove one or the other of the theories as to the origin of the disease, as there are numerous authorities well fortified with data on both sides of the controversy. It does, however, become essential in attacking this trouble for the operator to adopt one or the other of these views, and to direct his line of treatment according to his ideas of its origin. If this trouble is purely a neurotic one, with a constitutional basis for its development, then the line of treatment must be along measures which will correct the constitutional or the neurotic element before results can be obtained, and one must not expect to get results by treating it locally. After a long experience in the observation of these cases, of which I have seen a considerable number, the results of an examination of each and every one with a proctosigmoidoscope, taken together with the clinical symptoms, lead me to believe that in practically all cases this disease has its origin in anatomical changes of the mucosa, brought about by conditions which affect the intestines directly. The nervous symptoms which are associated with it I believe to be a result and not a cause of the disease, for in these examinations of the interior of the bowels, in every case of mucous colitis, I have observed decided anatomical changes in the mucous membranes, either of hypertrophy or atrophy of the glandular elements, or an associated mild inflammatory change. The conclusions which have heretofore been reached by the advocates of the constitutional or neurotic theory have been largely based upon clinical symptoms, with only the sparse material of necropsis, for death rarely if ever occurs from this disease alone. I feel sure, however, with the development of the direct examination of the bowel that more and more evidence will be accumulated to prove that anatomical changes are practically always present to account for the condition.

Again, to separate catarrh of the colon as a distinct disease from a membranous colitis, I believe to be a mistake, and I can do no better than to quote Cohnheim, who says membranous catarrh of the colon, which is still designated by some authorities as "myxoneurosis intestinalis," is rarely a simple chronic, reparable, superficial catarrh of the colon, which accompanies chronic constipation. Since constipation is associated with neurasthenia in a large majority of cases, particularly in women, it follows, therefore, that "membranous enteritis" is also met with in hysterical and neurasthenic patients. The neurotic theory contends that the mucous secretions and accompanying spasm of the bowels, with its pain, is purely an overstimulation from a highly sensitive nervous system, without any anatomical basis. Further, with successful treatment the neurotic symptoms have cleared up. Membranous enteritis disappears as soon as constipation is cured, and this is the best proof of the theory of its origin, since, notwithstanding the cure of constipation, the hysterias and neurasthenia often become still more aggravated and persistent. In other words we may find either present without the other. Mucous colic, or colica mucosa of Nothnagel, is an acute exacerbation of chronic membranous colitis.

These views of Cohnheim thoroughly agree with my observations. In other words, I can only think of membranous colitis as a later stage in the trouble, which began as a chronic, subacute or acute catarrh of the rectum, then hypertrophic, finally an atrophic colitis, which has progressively increased in severity and extended from the rectum to the sigmoid and into the colon. A continuous progressive disease, with names suggestive of distinct entities but in reality one and the same.

Having adopted this view of the trouble, I have directed my treatment along these lines. The method which I am about to relate has given me very encouraging results in all cases where there were no outside factors in the abdominal cavity which would keep up an irritation of the colon or rectum, or where it was secondary to heart, liver or kidney involvement.

A floating kidney rubbing up and down the vertical portions of the colon as it descends and ascends with respiratory movement, has been known to cause a subacute inflammation, as quoted by Tuttle; the removal or fixation of the prolapsed organ has relieved the catarrhal condition of the colon. Such a condition has not been within my experience.

Adhesions resulting from old inflammatory conditions, either attached to or running over the colon, sometimes cause obstructive stasis of the feces, so that the condition starts up an inflammatory state which, when relieved, permits the bowels to return to their normal condition, when proper treatment has been instituted.

A subacute inflamed appendix has been known to be a factor associated with mucous colitis, although it has been suggested by some that the appendicular trouble is a resultant of the catarrhal condition and not contrariwise. It is hardly necessary to go into the symptomatology of this trouble, as we are all familiar with its predominant symptoms of constipation, colic, intermittent diarrhea, with large or small quantities of mucus, either formed or unformed, mixed with cellular elements and small particles of fecal refuse, and in nearly all cases nervous or neurasthenic symptoms.

The visual picture through the proctoscope of the mucous membranes in the hypertrophic form with enlarged glands shows the mucous membrane congested, giving to it the characteristic granular appearance. In the atrophic form the glands are almost entirely obliterated and the mucous membrane presents a smooth, glistening appearance, with the small vessels coursing through it, clearly defined and sharply cut, a picture not unlike that made by

the vessels seen in the retina ophthalmologically.

The method I have been using in treating these cases has been by fuming crystal iodine, or one of its salts, forcing the fumes into the rectum and colon with slight pressure. In experimenting with a number of salts for vaporization by heat I found that iodoform was the one to give me the quickest and most easily controlled amount of vapor, but, owing to its ill-smelling character, it was very disagreeable to handle. I attempted to use thymol iodide, but this required a higher temperature to break it down and was not so satisfactory. I then resorted, as originally, to iodine crystals and have been using these since in my treatments. They are not so satisfactory as the iodoform in generating the fume, but are more agreeable to work with.

The apparatus consists of an ordinary 500 c.c. Florence flask, with a double perforated rubber stopper connected with pressure tank or bulb on one side, the glass tube entering into and extending to about 2½ cm. from the bottom of the flask, an exit being provided by a right angle glass tube with its inside end close to the top. The exit is connected with a short glass tip by rubber tube about 25 cm. long. The patient, if a man, is placed in the knee-chest position and, the proctoscope being introduced, the gas is blown through it into the bowels until the patient complains of cramps or too much distress. (If the patient is a woman she is placed in the Sims position.) The air is then allowed to escape and the insufflation is repeated, so that altogether the vapor from two grams of iodine crystals, or 1½ grams of iodoform, is used. The iodine is fumed by means of a small electric stove, placed under the flask; a bunsen burner or an alcohol lamp can be used; I did not find them so easy to regulate, but they are adaptable where electricity is not available. As fuming takes place at a slight temperature, not much heat is needed.

The glass tip inserted through the anus a few centimeters may be used without the use of the proctoscope in cases where patients grow weary of its insertion; but the proctoscope aids dilatation.

In the early stages of the disease this treatment is given each day for a period of ten days, and then at less frequent intervals so that the treatment extends over a period of six to eight or twelve weeks. The result has been that the constipation was relieved and the patient had regular normal stools. The mucous membrane assumed a more nearly normal appearance, and the mucous secretion ceased.

The preliminary treatment before the injection consists of the patient irrigating his bowels thoroughly, so that he presents a clean intestine, each time before his regular treatment. He is instructed, of course, along the line of diet and regular habits, as I believe that unless the constipation itself is relieved the primary factor in the disease is not removed. The benefit of the treatment is two-fold. First of all, the intestines are dilated gently by the pressure of gas within them. If there is a tendency to ptosis, it lifts them up into their normal position. At the same time the deposition of the iodine occurs throughout the entire bowel and acts as a local agent just as we use it as a local antiseptic or alterative for the mucosa in any part of the body. In other words, this is a method of making a direct application of the iodine to parts of the body which are ordinarily unreachable.

In confirmation of the fact that the iodine is deposited throughout the bowel, before adopting this method of treatment, with Dr. Spencer, my then assistant at the Baltimore Medical College, I experimented upon dogs, injecting the gas by a similar apparatus, killed the dogs, and tested for and found the iodine throughout the large bowel. Indeed, we found that the iodine was deposited in a large degree quite far up in the small intestines. But we can hardly expect this to reach so far in the human subject, because doubtless a greater amount of pressure was used than a patient could stand.

It also became of importance that we should know whether there was a possibility of rupturing the intestines. We removed the intestines of a dog and found that the rupture did not take place until a pressure of some 417 mm. of mercury was reached. Before any such point as this is reached in a human subject the patient begins to complain so much that we have a danger signal long before there is any real danger.

In further confirmation that the iodine vapor does pass up through the colon, I took occasion to use it in a case in which I had done an appendicostomy, and I found that the air escaped through the opening of the appendix with a distinct iodine odor. Again, to show that there is no danger in cases of ulceration, I used it in two cases in which there was extensive ulceration of the colon, one of tuberculous and the other of syphilitic origin. The patients felt no untoward effect, nor did the treatment apparently give any beneficial results. I feel, therefore, the method is a perfectly safe one, and the cases I have thus treated were markedly benefited and the majority were apparently cured.

Case I.—L. S., a child five years old, parents both healthy giving no unusual condition except the father when he was a child, had a tuberculous knee, which was left ankylosed. The little boy developed colitis with the usual symptoms of alternate constipation and diarrhea and abdominal distress, also discharge of mucus. He described his pain in a most graphic way when he said his stomach "fretted" him. Upon examination he showed the usual condition of mild congestion. The neurasthenic or depressed condition, so often associated with this trouble, was remarkably shown on one occasion, when this little fellow, who was of a very cheerful disposition, came into the house crying over the fact that his father had neither father nor mother as he had. Another occasion he was overcome by grief, because of his father's lameness, a condition which had existed all of the child's life. The depression entirely disappeared with the relief of his colitis.

Case II.—Captain E., aged 54 years, army officer. Lived many years in the West Alkali country, drinking the water. Developed marked constipation, followed by distress over ascending, transverse, and descending colon. Some tenderness over the appendix. The appendix was thought to be the cause of the trouble and was removed six years ago, in Philadelphia. He was confined to the hospital and was treated over a period of three months, then he left the hospital not at all improved. When I first saw him he complained of abdominal tenderness and soreness, and accumulation of gas and intestinal colic. This would be relieved by cleaning the intestines out with oil. Proctoscopic examination of the rectum and sigmoid showed it to be a case of atrophic proctitis and sigmoiditis, extending throughout the visible tract. The surface was glistening, the mucosa was thinned out to the extent of practically obliterating all the crypts, the small blood-vessels were prominent and under the mucosa looked not unlike the picture one sees of the retina when viewed through th ophthalmoscope. From the presence of mucus coming down in large lumps and strings I diagnosed the condition as atrophic colono-sigmo-rectitis and treated it accordingly. I made every effort to regulate the bowels and correct constipation, for which I used high injections of olive oil, 1½ liters at night, cleansing the lower bowel next day with salt solution and topical applications of extract of krameria. This benefited him greatly, but as soon as treatment was suspended his old symptoms returned. I then began to

use iodine vapor, distending the colon thoroughly. This treatment was continued over a period of six weeks, the amount of mucus was decreased, the bowels became more regular, distress from gas was relieved and the patient had fewer attacks of colic. His general spirits were better. His condition was materially improved, when he was transferred from Baltimore.

Case III.—Mr. W., aged 24 years, medical student. He gave a history of mucous discharges and constipation, covering a period of five years, following an attack of typhoid fever. There were the usual symptoms of colic, constipation, and general malaise with tenderness especially over the caput ceci and sigmoid flexure. Of especial interest were two attacks of accumulation of something in the colon, one described as a lump in the right side, the size of a large orange, which remained for over a month, and disappeared eventually, but with marked intestinal colic; doubtless this was a fecal mass. Another, not so large, occurred on the left side, several months later, with similar history. The examination abdominally and proctoscopically, showed his case to be one of atrophic colitis with ptosis of the colon. No treatment other than iodine vapor was used over a period of thirteen weeks, with entire relief, with no recurrence, now after a period of over a year.

Case IV.—Mr. R., aged 34 years, a clergyman, who was compelled to give up his ministerial duties because of nervous prostration and neurasthenia. He came to me after taking rest cures, milk cures, and stomach lavage. His symptoms were those of mucous colitis, marked depression, weak spells, sense of impending breakdown. The treatment given him cleared up the intestinal symptoms, relieved his constipation when aided by 5 minims of tincture of belladonna. While he has not yet taken charge of a church, he has repeatedly filled pulpits for other pastors, without any recurrence of his nervous manifestations. He still complains of some tenderness over his appendix, which I believe is subacutely inflamed, and have advised its removal; this he has not consented to do.

I believe his case one of colitis, reflexly set up by an inflamed appendix, which, while it has been relieved by the iodine vapor, will, I think, recur in the course of time unless his appendix is removed.

These several cases illustrate three types, with the cardinal symptoms of mucus, colic, and depression.

Altogether I have treated thirteen cases presenting similar conditions with this method, in each instance marked benefit has resulted; and with exception of four, I feel that cures can be claimed for them, although time is necessary to show its permanency.

I therefore present these observations, believing they may be of some help in the treatment of a disease which does not yield readily to other means.

Vapor of iodine in other conditions has been made use of and I can claim nothing for originality along this line. The application of volatile drugs to the intestinal mucosa is a method which may readily be used, and I present it hoping that such use may be further extended.

THE EMPLOYMENT OF SKIAGRAPHY IN THE DIAGNOSIS OF ENLARGEMENT OF THE THYMUS GLAND.*

By D. BRYSON DELAVAN, M.D.,

NEW YORK.

Enlargement of the thymus gland, whether associated with the condition known as "Status lymphaticus" or otherwise, can no longer be called a pathological curiosity. Cases occur with sufficient frequency to have brought the subject prominently forward, and a considerable literature upon it has, during the past ten years, been developed.

*Read at the thirty-sixth annual meeting of the American Laryngological Association.

Indeed, there are few large clinics in which accidents due to this cause have not occurred to patients under operation. Diagnosis by ordinary means is often difficult, and the only intimation of trouble comes too late. Another difficulty lies in the relative infrequency with which illustrative cases present themselves to individual observers. The average clinical attendant may never have seen one until he finds himself confronted with the fatal occasion. Recently the skiagraph has been called into requisition, with results both valuable and interesting, as shown by the following cases.

Case I.—R. S., aged seven, of American parentage, a slender, anemic looking boy, with weak heart, contracted chest, and history of frequent attacks of illness. Both tonsils were enlarged and the upper pharynx was filled with a large mass of hypertrophied lymphoid tissue. His physician in Philadelphia had made the diagnosis of probable enlargement of the thymus gland. The symptoms due to the nasopharyngeal condition, however, were so urgent that, after a careful examination of the patient, we advised operation. The case was seen in consultation by Dr. Herbert Carter and Dr. Norton, of New York, who also failed to demonstrate the presence of thymus enlargement. In view of this difference of opinion a skiagraph was taken by Dr. Cauldwell, of New York. The picture showed the thymus to be absolutely normal. The patient was operated upon, Dr. Thos. L. Bennett administering ether. In the course of the operation nothing unusual happened, the growths were successfully removed, recovery was rapid and satisfactory, and up to the present time the child's condition has been all that could be desired.

Case II.—I am allowed to report this case through the kindness of Dr. John E. MacKenty, of New York. A child two years old was brought to his clinic to be operated upon for hare-lip. The patient's skin was rosy but white, his hair was scanty, the muscles of his neck were thick, his hips were large, and the body in general was too fat. The operation under general anesthesia lasted one-half hour. Six hours after operation the patient suddenly died. A skiagraph was immediately taken and an autopsy made. The autopsy showed an immense hypertrophy of the thymus, thus confirming the remarkably clear finding of the skiagraph.

I have presented these two cases because they seem to typify to a remarkable degree the value of the *x*-ray in deciding questionable conditions of the thymus gland. It would have been easy to secure an indefinite number of plates representing the same thing. The multiplication of examples, however, would add little to the weight of the argument already so fully sustained by these. Without doubt, the use of the *x*-ray before operation would result in the saving of lives. The examination of every child, therefore, would seem desirable. But it will be said the examination of all the children in attendance at a large clinic with our present facilities in the *x*-ray department would be impracticable, even if the fluoroscope could be depended upon. Unfortunately, at the present time, the fluoroscope seems out of the question, for there are several reasons which make it impracticable. A fluoroscopic examination would require at least twenty minutes of time, ten minutes being consumed in accommodating the eye to the dark room. Again, the struggles of the average child would make the procedure extremely difficult. Finally, even under favorable conditions, recognition of the conditions present in the examination of this part of the body in the infant is often impracticable.

In view of this, dependence must be placed not upon fluoroscopy, but upon the skiagraph. A good skiagraph, skilfully taken and well interpreted, will give far the best information. Here again we are

confronted with difficulties. The ideal conditions would obtain, of course, in private practice, where expense might not be an obstacle and where the services of a good *x*-ray specialist would be at command. Even here the way is not always clear, even in the matter of expense.

In clinical practice the making of skiagraphs at the rate of say twelve a day would require the equipment and services of a full department as such matters are now organized and conducted in our best hospitals. Take, for example, the *x*-ray department of St. Luke's Hospital, New York, one of the most complete in the country. Under its present conditions it is fully capable of executing the work of a large general hospital. For it to meet the demands of an out-patient clinic of even moderate size would require the practical reduplication of the staff and plant, of course, at great expense. Granting the value of skiagraphy, how, then, can it be made a practical resource in this connection? As a matter of fact few clinics are connected with institutions supporting an *x*-ray department, and as we have already seen, such a department adequate to the other needs of the institution would be overwhelmed by the flood of work thrown upon it by the throat clinics.

The answer to this would seem to be, first, in the possibility of so reducing the expense of skiagraphy as to bring the use of it within more reasonable financial limits. Next, to simplify the process, especially to the end that less time be consumed in the execution of the work. Finally, to impress upon the minds of the managers of hospitals the value of skiagraphy in this class of cases, and urge that as far as possible proper provision be made for attending to them.

Again, since to examine all would be impracticable, it should be urged that in any suspected case an *x*-ray examination be made before operation is attempted.

In conclusion, careful instruction should be given to clinical assistants, to the end that they be warned as to the dangers of operating upon patients having enlarged thymus, and that they may be made competent to diagnosis such cases when presented to them.

40 East Forty-first Street.

ALCOHOLISM AS A FACTOR IN DISEASE.

By DELANCY CARTER, M.D.,

NEW YORK.

Alcoholism, as a factor in disease, comprises, directly or indirectly, a great area. In fact comprehends the whole armamentarium of diseases and ills to which the human body is heir. This is a broad statement, and yet one that is so absolutely proven as to make it an axiom. The question naturally comes to us, why is it that alcohol causes such devastation to the human system? To prove this we must penetrate to the very vital forces which we call "Life"; those vibrating ions, which by means of their vibrations produce electrical energy, causing the different factors, which go to make up the whole, to perform their several functions in order that the vast machine, which we understand as life, may be complete in all its parts.

Alcohol is a protoplasmic poison. What is a poison? A poison is defined as any substance which acts on living cell and tissue to destroy their power and impair their activity. Alcohol has been shown, according to our latest authorities, to be distinctly toxic to the ameba, the simplest form of protoplasmic life. The action of alcohol on the cells, when saturated with different solutions, is typical of the effect on the higher factors of the human system. First narcosis, then paralysis and loss of action, which is death to the cell. This coincides with Prof. Kraepelin and his co-workers' idea of progression, that it is not the first drink, nor the second, nor fifth that intoxicates; it is the sum of the first, second, and fifth that intoxicates. Prof. Kraepelin makes out a very strong case against alcohol. He has been investigating for twenty-five years the psychic effects produced by drugs, with the view of getting a most comprehensive knowledge of the incipient symptoms and processes of mental disease. He wanted to find the least common multiple, as it were. To this end, with his wonderfully equipped psychological laboratory, he attempted, artificially, to produce on normal individuals simple sets of psychic derangements that he might study the various phenomena in their beginning and development, and apply the knowledge to the study of mental derangements. He used as drugs, bromine, caffeine, sulfonal, and opium but found alcohol the best drug to work with; therefore concentrated his efforts in that direction. With instruments of the greatest precision, he and his colleagues, some of the most eminent scientists in the world, established the fact that alcohol caused degeneration; that it affects all the faculties; the more definite and higher the faculties are, the more definite and measurable the results; also that the physiological and psychological action of alcohol is cumulative, and if continually used even in small doses the harm is increasingly manifested. They emphasized that the ordinary or average human being cannot preserve his stomach and brain in it for years without injuring both; that the powers of coordination are certain to be impaired, and the destruction of his tissue hastened.

The experiments regarding the effect of alcoholic solutions on cells are confirmed by a great variety of studies in other directions, showing that alcohol is a direct protoplasmic poison, and that this poisonous action is due to the retarding power of the cell to absorb oxygen. Other eminent writers have shown that alcohol is not only a narcotic and paralyzing agent of protoplasm in all forms, but also injurious to cell life.

We know that alcohol diminishes the vitality of the body, and the resisting power to overcome disease. An eminent London physician, Prof. Laitiner, brought out this fact very prominently with results of his laboratory studies, extending over several years, and in the examination of over three hundred persons showed that the normal resistance of the red blood corpuseles was diminished in all cases where alcohol was used, and that the bactericidal power of the serum against disease was very much impaired. The microscopical, pathological effects of acute alcoholic poison on the human system is practically unknown, as it is impossible to obtain material for these examinations in sufficiently fresh condition from cases of delirium tremens that have died from the effects of their debauches. We get the results from experiments on the lower animals treated precisely in the same manner, and these show that tissue changes in all the different factors that comprise the human system.

Alcohol is a chemical poison as well. The sensation of coldness when applied to the body is due to

its rapid absorption of water. When alcohol is taken in the mouth as a beverage, this dehydrating effect is so pronounced as to produce irritation. This would rapidly lead up to inflammation, therefore water is taken with it to counteract its corrosive action. And we can follow along its action on the mucous membrane of the throat, of those who commence the habit; follow it up to its inevitable conclusion. We find that the parts coming in contact with alcohol in the shape of the various concoctions combine with it.

After a time the parts become sodden, lose their sensibility until the paralysis is so great on the end plates and nerves of sensation that pure alcohol will not feel too corrosive for the confirmed inebriate.

This chemical absorption of water by alcohol extends to every tissue with which it comes in contact, until it reaches the point of saturation. The feeling of warmth in the stomach is the first stage of irritation which eventually extends to inflammation. The dehydrating property is very marked. An examination of the blood shows this in the shrunken blood corpuscles, and diminished number of phagocytes. The temperature is lowered, and the functional activity is reduced. While there are some organs which suffer more than others, the corrosive effect is not noticed in all the organs alike. The liver, kidneys, and brain tissues are the ones which show the most marked lesions, and this we can very easily understand from the nature of the function of these organs; in other cases they are less. So there is no question about the conditions which follow the use of alcohol; absorption of water from cell and tissue; the degenerative changes that occur from the coagulation of the albuminous particles; the deposit of fibrin, and the pronounced disturbance of the balance necessary to carry on the uniform workings of the vast machine known as the human body.

The effect of alcohol on the circulation is most marked, the increased action of the heart, the hyperemia of the face, and many other signs. We can measure with great precision the rise and fall of the heart's action. The muscular output, from the increased action of the heart, is followed by a similar diminished output in the exact ratio to the high level which it has attained. This toxic action, due to the suspension of the control centers and vaso motor paralysis, can be studied on the mucous membrane and the congestion of the face, and it extends to the liver, kidneys, brain, and all vascular organs.

The physiological effect of deranging and paralyzing the circulation of the blood in the veins and arteries is followed by a diminished absorption of gases, defective distribution of nutrient plasma, and obstruction in the eliminating of the waste products. The result is depression, fatigue, and finally organic changes due to poisoning and starvation.

The effect of alcohol on the brain and nervous system is most marked. Prof. Kraepelin began a series of observations to determine the effects of alcohol on the brain and nervous system. He assumed a normal standard of sensory and mental activities in different individuals; then gave spirits and compared these conditions with what existed before, so as to determine the exact action of alcohol on the person. These experiments were carried on for many years and indicate with uniformity that alcohol in small doses both impairs and diminishes the activity of the senses and that the derangement is measurable, although not recognizable by the person operated upon. Thus a person able before the use of alcohol to distinguish letters or hear sounds at a certain distance, after the use of alcohol suffers the impairment of both vision and hearing. This impairment can be stated in exact figures.

Spirituous liquors contain from 40 to 56 per cent. alcohol; sherry, madeira, and port, 18 to 20 per cent.; Silician wines, malaga, and moselle, 16 to 20 per cent.; champagne, 9 per cent.; Rhine wine, 10 to 12 per cent.; clarets, 9 per cent.; malt liquors and ale, 5 to 8 per cent.; beer, 2.5 to 5 per cent. of alcohol. Spirituous liquors may be considered as acting in ratio to their alcoholic content; wines vary in their acting either from the ethers which they contain or in some instances as far as digestion is concerned in proportion to the solid matters, rather than to their alcoholic content, which does away with the old impression that alcohol is a digestive stimulant.

On studying the effects of alcohol on the digestion, we find that it stimulates the flow of saliva, and also the concentration. In large quantities alcohol is positively toxic, retarding and even preventing digestion, and protein metabolism in particular. It is evident that although alcohol may be used by the body for energy, the metabolic changes are not similar, and it must be a question of some moment from whence the body draws its energy, whether it is from alcohol, fats or carbohydrates; it is evidently possible for the body to use alcohol as a food product but the changes in metabolic results show that while being consumed as a food, alcohol may simultaneously exert its drug or toxic action. The possibility of alcoholic action in the increasing of muscular action is not definitely settled. The possibility shown of alcohol in moderate doses furnishing energy for muscular work is a far different question from the possibility of alcohol as a part of the diet for muscular labor. General observations and results of practical tests on a large scale show such beverages to be of doubtful value or even harmful. Alcohol apparently increases the power of fatigued muscles, although it does not restore them to the same power that they had before the fatigue. It is only temporary and of short duration, followed by greater fatigue, which more alcohol stimulates until the parts become paralyzed and unable to respond to any stimulants. Alcohol will thus enable a short spurt to be made, but it will not give sustained muscular power and it is followed by a depression of energy below the normal.

Besides functional disorders which alcohol produces, other more serious and permanent tissue changes take place. There are at least three distinct changes following the use of alcohol—fatty degeneration, atrophy or shrinkage of the tissues, fibrosis or fibrous thickening of the organ. According to Dr. Campbell of London, these changes, as might be expected, are generally more pronounced in the alimentary canal and in the liver, but no tissue is exempt from these changes. The result is a permanent organic disease which is never entirely curable. This is the real nature of the chronic gastric catarrh from which the drunkard is liable to suffer. The stomach wall itself has become permanently diseased and a varying portion of its glandular organs have been destroyed; sometimes ulcers form in the wall and give rise to much pain and distress; later cancer may develop on the site of these chronic ulcers or in the scar that is left

behind. The net result in any case is a distinct weakening of the normal power of digestion.

No digestive organ suffers more than the liver from the pernicious effects of alcoholic drinks. The first step is congestion as a result of the irritation which is set up. This congestion is followed by atrophy or shrinkage and more or less fatty degeneration. The most striking change is the marked increase in the fibrous tissues which constitute the supporting framework of the organ. Normally there is just enough of this tissue to hold the organ properly together and maintain its natural form. The abnormal increase of the supporting tissue takes place at the expense of the glandular or working tissue of the liver, and the direct result is that the liver is steadily and gradually reduced. Ultimately the organ becomes shrunken in size and often presents irregular nodules, giving rise to the name Hob-Nail or Gin Liver. In the later stage the liver slowly and permanently loses its function and finally becomes a useless organ. The use of alcoholic beverages leads to the formation of abcesses in the liver, and on acount of its irritating effects may finally produce a malignant disease. Alcohol, so far as the digestive organs are concerned, not only interferes with their digestive function, but also destroys their natural power of protecting the body from disease.

The action of alcohol on the brain is still a subject for dispute. Binz holds that alcohol first stimulates then depresses. Schimiedeberg, Bunge and others that the apparent stimulation of alcohol is a paralysis of the higher functions, and that alcohol depresses from the beginning. Kraepelin claims to have proven by his experiments that in the early stages of its action, alcohol stimulates the motor functions of the brain, but all reactions requiring nicety of judgment are dulled even by small doses. Kraepelin has also shown that small doses diminish the accuracy and ability to add numbers, or to learn numbers by heart. Smith has shown that this is especially noticeable when small doses of alcohol are taken daily, and that when the alcohol is cut off the ability to add and memorize returns. It is also noticeable that the tendency to erroneous judgment is increased, the subjects experimented upon believing that they had performed their reactions under alcohol, when as a matter of fact, the reactions were diminished in accuracy and rapidity. Alcohol in moderate doses does not increase the quality or vigor of mental processes, and the flow of ideas with the feeling of mental richness is due to the removal of normal inhibition. Alcohol clearly tends to lessen the power of clear and consecutive reasoning and lowers the acuteness of the senses. After large doses the judgment is lost, the power of self control and will are in abeyance, all idea of proportion is gone, the sense of responsibility and restraining impulse is destroyed, and finally the motor power for speech and motion disappear, and torpor and coma supervene. The result of the continued action of large doses is the permanent loss of these mental functions, and the chronic alcoholic becomes an irresponsible animal. Since Austia has classified alcoholism as a nervous disease, it has so been generally considered.

In the heart we find lesions resulting from direct poisoning and from associated conditions. Fatty degeneration of the muscles is the common lesion, brown atrophy combined with fatty degeneration is the second most common, brown atrophy alone is the third, and fibroid myocarditis is the fourth. There are often various combinations of the above lesions, and while fatty infiltration is said by most observers to be more common than fatty degeneration, the reverse held true in others. That brown atrophy of the cardiac muscle is caused by alcohol seems to be true, for after excluding all cases in which carcinomas are present, and in which there was any sign of healed or active tuberculosis, in 125 cases there remained 23 hearts from individuals under fifty-five years of age in which this degeneration was present. The secondary effect on the heart is shown through the circulatory system, and from disease of the coronary arteries we obtain fibroid myocarditis, and in the enormous hearts of beer drinkers, which are produced by the large amount of fluid passing through the blood-vessels. The arteriosclerosis produced by alcohol or secondary to the kidney lesion produced by it, is also the cause of cardiac hypertrophy and later of fibroid myocarditis. Alcoholic poisoning is usually considered as a cause of arteriosclerosis and atheromatous degeneration. Lanceraux states that atheroma of the aorta and vessels is rare in alcoholism. The experience in this country is the reverse. It is characteristic of arteriosclerosis that the lesions are unevenly distributed in the body and the peripheral arteries may seem unaffected while the aorta or central arteries may be extensively degenerated. Atheromatous degeneration is a frequent cause in alcoholism of anurism, apoplexy, and embolism. Cabot, in studying the frequency with which arteriosclerosis may be made out in the radial arteries in alcoholics, comes to the conclusion that it is noticeably present in more than 67 per cent., but the atheromatous degeneration from alcohol is more commonly present in the aorta and the vessels, although it is sometimes extensive in the aorta and but slight in the vessels of the neck, and in other cases the reverse is true. The aorta and the other vessels may show slight atheromatous changes and yet the coronary arteries be extensively calcified. In 53 men dying under 50 years of age, atheroma was extensively shown in 9, moderate in 26, slight in 14, and absent in 4. In 19 women atheroma was extensive in 6, moderate in 6, slight in 6, and absent in one. The most common condition in the lungs are edema, congestion, and various forms of pneumonia, such as lobar, bronchial and septic. It is also common to find tuberculosis in various stages. The old idea that alcohol is a preventative is proven to be unfounded, and it is unquestionably true that alcohol reduces the resistance of the body and distinctly predisposes to tuberculous infection. Pulmonary emboli from cardiac thrombosis and embolism of the pulmonary arteries are also found. The liver has always been considered as especially prone to show changes from chronic alcoholic poisoning, with fatty degeneration and cirrhosis, as the two special forms of degeneration. The enlarged cirrhotic liver seems to be the most frequent, and the true biliary, the least frequent. Clinical experience in Bellevue Hospital, New York, suggests that the extreme degree of cirrhosis does not occur as commonly as it did twenty years ago; this is accounted for by a greater consumption of malt liquors.

In the spleen chronic congestion and fibrosis are the two most common pathological conditions. Other conditions in their order were, acute congestion, brown atrophy, amyloid degeneration. In the pancreas the great frequency with which fibrosis occurred was very noticeable. The effects of alcohol on the kidneys is the one marked factor in disease.

It has been frequently demonstrated that the urine after a single alcoholic excess, often contained abnormal elements indicative of transient irritation or of slight inflammation.

Kuhlden has shown in his animal experimentation that there is fatty degeneration and necrosis of the renal epithelium, hyperemia of the veins and capillaries with hemorrhages, and he considered that with longer duration of the experiment chronic interstitial nephritis would appear as a result. Formad found in alcoholics who died suddenly a marked hyperemia of the kidneys with noticeable enlargements in beer drinkers, the enormous amount of fluid taken produces a functional hypertrophy when arteriosclerosis has developed, the chronic forms of kidney diseases necessarily follow. It was noticeable that in all the autopsies made there were no normal kidneys. Chronic parenchymatous nephritis was the most common, next in order was chronic interstitial nephritis.

The stomach shows various abnormalities due to alcoholic poisoning, chronic gastritis being the most common. An inflammation of the gastric mucosa covered with mucus is common in acute alcoholism and the acute sooner or later goes into the chronic form. The bladder is very apt to be distended in those who have died suddenly, and over 25 per cent. of both sexes were found in autopsy to have chronic cystitis.

That alcohol produces sterility is well known, well-marked atrophic changes being shown in the ovaries on examination. In the men the testicle did not show such great changes, although some under the microscope showed sclerosis. Lancereaux has proved this, and Simonds observed that 60 per cent. on post-mortem examination showed azoospermia.

It has long been noticed that alcohol has a special affinity for the higher nervous centers, and especially for those coming in the clinical aspect of the disease. Inherited or constitutional defects cause great variation in the effects of alcohol on the individual nervous system, and it is difficult to estimate between the lesions caused by alcohol in previously normal persons, and those inheriting various defects; that a previously weakened nervous system will show earlier and more extensive lesions seems logical, and is true, but the idiosyncrasies of normal persons to alcohol present great variations. Serious nervous diseases are produced by alcohol in persons of previously normal constitutions; some individuals will die of somatic degeneration and retain normal cerebral tissue, while in others the brain and spinal cord seem to suffer early. The lesions in the central nervous system seem to be brought about either by degeneration of the cerebral arteries or from direct action of alcohol on the nerve cells; the latter is the most probable reason. Edema and congestion of the membranes are usually present and were found in 72 per cent. of the cases of men's brains examined in autopsies, and 51 per cent. of the women's. Adhesions of the dura to the skull, with an increase of the pachionian bodies are common and very frequently there is thickening and adhesion to the "pia mater." Clinical experience demonstrates the fact that cerebral degeneration from alcoholic excesses is more common among women than among men. Microscopical examination of the cerebral tissue shows an intense degree of atheromatous degeneration of the minute vessels which are enlarged, tortuous, unevenly distended usually by fusiform dilatation, and their tissues covered with nuclear proliferation. About these vessels the spider or glia cells are crowded in great abundance. These so-called scavenger cells form with their branching processes a thick connective tissue belting, densest just underneath the pia, converting the outer fourth of the cortex into a closely walled layer, much diminished from the normal thickness, and often closely mapped off from the under layers. Sometimes the cellular elements of the glia predominate, but in later cases many of the protoplasmic masses have disappeared, leaving a dense connective tissue structure in which the remaining nuclei are thickly sprinkled. The perivascular spaces are often filled with lymphoid cells. The axis cylinder shows a loss of medullary investment and is itself greatly swollen and often irregularly fusiform. The white matter of the cortex shows equally extensive atheromatous changes in its vessels, and in the fusiform and sacculated dilatation are seen deposits of hematodin granules; not infrequently the vessels are plugged and the diseased wall found ruptured with extravasatious blood and hematodin crystals in the surrounding areas.

The changes found in the spinal cord are similar to those found in the cerebral cortex; the vessels of the posterior and lateral columns are more involved than those of the anterior columns. The characteristic change is an obliterating endarteritis, the lumen of the vessel being encroached on to such a degree that the intima is thrown into ridges.

The pia of the cord often shows thickening and evidence of inflammation and extension downwards of cerebral pia mater or a coincident chronic inflammation. The connective tissue processes from the pia into the cord are thickened, the media raphé of the posterior columns and the peripheral zone of the cord being the area of election for the sclerotic processes. The paralysis produced by peripheral neuritis was described by Magnus Huss as due to lesions of the central nervous system. The acceptance of the neuron theory has caused us to revert to the ideas of the older writers and realize that in the majority the neuritis of alcoholics is of central origin.

That alcohol reduces the resistance to infectious diseases is well known and generally recognized. Bares clearly shows that in epidemics of cholera the disease claimed the majority of the alcoholics, and when they were attacked the chances for recovery were comparatively small. In pneumonia the mortality is by far greater than the average. In 1,100 cases in Bellevue Hospital in 1904 over 50 per cent. of those who gave a history of alcoholism died, and this was the ratio in all the other hospitals where the statistics were gathered.

The moderate use of alcohol is a relative term, moderate for one may be excess for another, and the popular fallacy that moderate drinking can always be kept within the bounds of safety and sobriety, and left off any time, has ruined more lives than the white plague. As a rule, all habitual drunkards were once moderate drinkers. The accustomed dose under normal conditions will not be sufficient under abnormal conditions. In my extended experience the habitual drunkard in the great majority of histories commenced with the flattering assumption that he would be immune from the habit, even when the amount consumed was getting slowly but progressively larger, until the subconscious moderate drinker became the conscious habitual drunkard, and he awoke to the fact that his mentality was weakened and his will power

gone. The result of chronic alcoholism does not end with the individual, the children often come into the world handicapped as idiots or weak-minded.

Howe, in Massachusetts, found that 145 out of 300 idiots were descendants of drunkards; Beech in England, found in 430 idiots, 31 per cent. were children of alcoholics. This ratio was found prevailing in the statistics of all the European countries.

The diseases that are traced directly to and are caused by alcohol may be eumerated as follows:

Dilirium tremens is the most important. This develops as the result of chronic alcoholism, and its occurrence does not run parallel to the amount taken, for idiosyncrasies are strongly marked here. Dilirium tremens develops after a suspension of a bout of heavy drinking. Symptoms of insomia, with restless, broken sleep, tremulous hands, extreme depression of spirits, frightful imaginations of horrible hallucinations of sight and hearing prevail. There is a condition of chronic alcoholism, but more especially following acute and chronic delirium, which is rarely noted. Dana is the only one who describes it; he calls it wet brain alcoholism or serous meningitis, there is no true inflammatory process but an extensive transudation of fluid in the meninges.

Acute hallucinosis of drunkards or acute paranoia, or acute persecutory insanity, this is closely related to dilirium tremens, and there are cases which seem more like connecting links than belonging clearly to one or the other. The patients suffering from this form of alcoholic psychosis are generally younger than the delirium tremen type. Chronic alcoholism is also counted as a separate disease. The amount of liquor when taken daily will produce the lesions and symptoms of chronic alcoholism, varies with the individual; most men who partake of moderate doses, dilute their alcohol with large amounts of water, and the effect produced is less than when taken in concentrated forms; but when once the condition of chronic alcoholism is developed the following symptoms result: weakening of the will power and blunting of their normal natures, they become untidy and slovenly in their personal habits, careless in their ways of doing things, doubtful about promises, a lack of responsibility to the community as citizens, ceasing to care for the ordinary decencies of life. Alcohol more than any other drug can reduce a man from a standard of honor to the lowest depths of depravity and lack of moral perception. This is more particularly noticed among women, due to their different temperamental characteristics.

Dipsomania or periodical inebriety. In some cases alcoholism exhibits itself in the form of periodical attacks. These patients are often total abstainers between attacks, and struggle against the desire when it comes on. Some authors believe these attacks are related to periodical epleptical explosions. Thelat defines the chronic alcoholic as one who becomes drunk whenever the opportunity offers, and the dipsomaniac as one who becomes drunk when the attack seizes him.

Alcoholic trance, automatism, or pathological drunkenness occurs in psychopathic, hysterical, or epileptic patients, traumatic injuries to the skull, or after a sunstroke. Alcohol produces disturbances of consciousness, which deviate from the ordinary sequences. The same condition has been seen in those who have been injured through the excessive use of alcohol. One of the simplest expressions of this condition is that where the patients after using much smaller amounts of alcohol than formerly, become drunk and are utterly oblivious the next day to everything that had occurred. In the more pronounced cases they lose their identity or knowledge of their environment while on a debauch, and find themselves in a distant city, all occurrences from the time they started or began their debauch, until coming to themselves being a total blank. The better name for this condition is alcoholic amnesia.

Korsakoff's psychosis. For many years there has been recognized among alcoholics a condition of delirium combined with polyneuritis; this was finally classed as a distant and separate psychosis by Korsakoff, and is now generally called Korsakoff's psychosis or syndrome. Mentally there is a loss of orientation and a marked defect in the power of retention of new impressions, and loss of memory for the recent past, and also for events during various periods of the patient's life; there is a strong tendency to confabulation, and to fabrications of the most absurd character, and even hallucinations together with polyneuritis. This usually occurs in the prime of life, and is said by some authors to be more common among women.

Arteriosclerosis. Alcohol as well as other poisons plays an important part in this disease. They may act, as Traube states, by increasing the peripheral resistance in the smaller vessels, in this way raising the blood tension or possibly altering the quality of the blood and rendering more difficult the passage through the capillaries.

Acute and chronic gastritis, acute hemorrhagic pancreatitis, aortic and mitral incompetency, and nearly all the heart murmurs are the common result of chronic inebriety. Out of 150 cases of cancer of the stomach, 77 gave a history of chronic alcoholism. Chronic parenchymatous nephritis is caused to a great extent by continual consumption of alcohol, as is chronic interstitial nephritis in conjunction with arteriosclerosis and cardiac hypertrophy. Polioencephalitis results from chronic alcoholism. Alcoholic cirrhosis of the liver is one of the most common of the functional diseases of the organ, the reasons for this form of disease having been fully explained by the action of alcohol on the cells, then tissue changes, and lastly degeneration of the parenchyma. Alcoholic neuritis is a special form of nerve disorder due to alcoholic poisoning.

According to Dr. L. D. Bulkley of New York, alcohol has a prejudicial effect on cell life, both vegetable and animal, and pathological studies have demonstrated degenerative changes in almost all the tissues of the human body as a result of alcohol taken internally. It is natural, therefore, to suppose that the skin suffers with the rest of the body, and clinically this is shown to be the case, often from the moderate use of alcoholic drinks. A great consideration in regard to the effect of alcohol in connection with diseases of the skin relates to its effect on the capillary circulation. All experiments and observations show that by its sedative action on the vasoconstrictor center of the medulla alcohol causes a slight paralysis of the nerves controlling the capillaries of the skin and the sense of flushing after its use in any quantity is well recognized. This dilatation of the cutaneous capillaries leads to a greater flow of blood to the surfaces of the body, and, of course, to a greater congestion of the diseased parts, which congestion is one of the chief features in many dermatoses, most difficult to con-

trol. With this congestion there is also an increased action of the perspiratory glands, with modified secretion. Another result of alcohol is to be mentioned which may have some bearing on its influences in diseases of the skin, namely, to its effect on the muscular tissue. Finally we have to consider the effects of alcohol upon metabolism and the final results of both anabolism and catabolism, which have so much to do with many diseases of the skin.

The following diseases of the skin are directly or indirectly influenced by alcohol. Syphilis. One of the first to dwell specifically on the effect of alcohol was Renault, who speaks very strongly in regard to the harmful influence of alcohol in syphilis, which is now a well recognized fact. Rosacea. Perhaps the most striking illustration of the effect of alcoholic drinks on the skin is found in the well-known acne rosacea of drunkards. Acne. Another disease characterized by redness and enlargement of the capillaries of the face. Eczema, psoriasis, erythema, and angioneurotic edema are among the remaining skin diseases which can attribute considerable of their severity to the continual use of alcohol.

Among the diseases of the eye which are influenced by the use of alcohol are: Acute and chronic conjunctivitis, amblyopia, amaurosis, and keratitis. That alcohol has a disturbing influence on the tissues of the eye, ear, nose, and throat is only expected from its effects on the tissues of the body.

Alcohol has a selective affinity for those cells which are most highly responsive to stimuli. The neurons are such cells and are universal in their distribution throughout the body. This affinity may show itself as a disturbance of cell metabolism, or again as a chemical reaction, but in either case the result is the same, functional irritability, cellular overstimulation, and eventual destruction from actual organic changes being easily demonstrable. The eye with its peculiar highly differential elements, its close cerebral connections, its great vascular supply, experiences alcoholic activity, first by disturbed, then distorted, then diminished, and finally loss of vision. The effect of alcohol on the mucous surfaces of the eye is associated with the same conditions with the nose, ear, and throat.

The ear, situated as it is in an unyielding bony case, with its peculiar nervous and lymphatic development, its close cerebellar association, is also sensitive to alcoholic influences, as illustrated in nystagmus, vertiginous symptoms, and the various ataxias.

The nose with its mucous surfaces is also very sensitive to alcoholic irritation, congestion, inflammation, hypertrophy, hyperplasias, and accessory sinus activities, and often an atrophy with ozena. The throat, pharynx, and larynx yield from a double attack, first the point of entrance directly, and the nervous, vascular, and lymphatics indirectly and reflex results following its absorption. The peculiar vocal effect of laryngitis and eventual establishment of chronic inflammation along the whole respiratory tract may result from the use of alcohol. Furthermore, the lessened resistance of the tissues furnish a fertile field to bacillary attack and tuberculosis. Syphilis, sarcoma, and carcinoma are concomitant results of alcoholic activity. Finally, in all eye, ear, nose, and throat work alcohol holds in many cases a direct relation, and in all cases is a contributing element in its pathological results.

THE DIAGNOSIS OF TYPHOID FEVER.

By G. A. RUECK, M.D.,

NEW YORK.

The notion has become prevalent that an early diagnosis of typhoid fever is generally difficult, and sometimes impossible. It is difficult indeed if one relies upon the symptoms described in the books as being of most importance, which are: the course of the temperature, the diarrhea, the character of the diarrheal discharges, tenderness and gurgling in the right iliac region, tympanites, and the eruption.

The value of these highly praised early diagnostic symptoms is very questionable, because: The temperature is only in exceptional cases an aid to diagnosis after the patient has been under observation for several days. Diarrhea does not occur at all in many mild cases, and in most cases the patient has taken laxatives or enemata before the physician was called. Iliac gurgling is not peculiar to enteric fever alone, and occurs even in healthy persons. Tympanites and tenderness may occur in many other diseases besides typhoid fever. The eruption, a very important sign, does not appear until five or six days after the onset of the disease, and is absent in many cases.

Which, then, are the means of making an early diagnosis of typhoid fever in order to apply modern means of treatment, as vaccine therapy and high caloric feeding?

1. Do not neglect at any time to consider the possible presence of typhoid fever in case you are consulted by a patient who has been "indisposed" for several days.

2. Usually the first and by far the most common symptom of which patients in the early stage of typhoid fever complain is headache. Whenever a patient complains of headache which has lasted several days the physician ought to think of typhoid fever.

3. The next thing to do is to count the pulse, which will generally be found to be slightly accelerated (84 to 110).

4. Then one must take the temperature and count the respiration. If there is elevation of temperature, acceleration of pulse with the normal ratio of respiration to pulse, *i.e.* 1-4, and a continuous headache, typhoid fever may be strongly suspected.

5. Next inquire if the patient has had chills occurring frequently and irregularly for several days.

6. Nosebleed is an occasional early symptom of little significance.

7. The most scientific and accurate way of making an early diagnosis of typhoid fever is by means of a blood culture demonstrating the presence of *B. typhosus* in the blood.

The diagnostic agglutination reaction of Greenbaum-Grübler known best, although undeservedly, as the Widal reaction, appears rarely before the beginning of the second week, and is therefore a late symptom of typhoid fever.

Differential Diagnosis of Typhoid Fever.—In rare instances typhoid fever may simulate cerebrospinal meningitis, or acute nephritis, or the infection may be very severe from the start, and take the character of a profound septicemia. It may simulate malaria, from which it is distinguished by the temperature curve and the examination of the blood. A diagnosis of typhoid pneumonia, *i.e.* a pneumonia caused by the typhoid bacillus and of typhoid-malaria (a double infection due to *B. typhosus* and the malaria parasite) should not be made unless their presence is demonstrated by

laboratory tests. From miliary tuberculosis and tuberculous peritonitis, it is distinguished by blood cultures, by the Widal, and the tuberculin tests.

Chronic and acute pulmonary tuberculosis are sometimes mistaken for typhoid fever, but in these conditions thoracic symptoms are more marked, variations of temperature are less regular and more extensive, and sweating is more common and more profuse.

Appendicitis is sometimes mistaken for typhoid fever. A careful physical examination, and, if need be, an operation will decide the question, for it is better to remove a normal appendix than to mistake a diseased appendix for typhoid fever. In appendicitis no time should be wasted by laborious blood examinations.

Chronic ulcerative endocarditis may be very similar to typhoid fever. Its differential symptoms are chills, irregular fever, substernal pain, endocardial murmurs, no rose spots, no abdominal symptoms, a more or less leucocytosis, the absence of the Widal reaction, and positive blood cultures showing other organisms than *B. typhosus*.

Catarrhal enteritis may be differentiated from typhoid fever through the absence of epistaxis, bronchitis, high fever, enlargement of spleen, and rose spots. Blood cultures and the Widal test will be found to be negative.

A lobar pneumonia which is a septicemia with a localized process of acute inflammation in the lung may be the beginning of typhoid fever, or, if caused by the pneumococcus or another organism or by a mixed infection (two or more organisms) may cause a toxemia like that of typhoid fever. The differential points are daily physical examinations of the chest and abdomen, a careful study of the pulse and respiration, especially of their ratio to each other, and the examination of the blood (agglutination tests and blood cultures).

Other diseases simulating typhoid fever are:

Epidemic influenza.—In this disease the temperature is usually not so long continued; there are no rose spots, a negative Widal, and the Pfeiffer bacillus is ordinarily present in the blood.

Uremia.—This is characterized by the absence of rose spots, and the Widal reaction. The urine shows diseased kidneys. The condition of the heart and arteries, and the previous history are suggestive.

Severe cases of trichiniasis.—The patient gives a history of having eaten salted or raw pork. There is edema of the eyelids, swelling and pain of the muscles, dyspnea and eosinophilia. A piece of the deltoid muscle for the examination for trichinæ should be obtained.

Typhus fever.—This is rare. The onset is sudden, the delirium early, and the stupor profound. The fourth day a macular and petechial rash appears which lasts 12 to 14 days. The disease terminates by crisis. There should be a blood examination. The diagnosis of this malady has been put on a scientific basis by the discovery of the bacillus of typhus fever by Dr. Harry Plotz of Mount Sinai Hospital, New York City, and is easy in epidemics after the diagnosis of the first cases has been made.

Relapsing fever.—There is a sudden onset, with chill and intense general aching. The duration of a single attack is six to seven days. The temperature falls suddenly below normal, and the attack is repeated in a week. Three to four relapses may occur. Blood examinations reveal the spirillum of relapsing fever.

Of late it has become very fashionable to label blood infections simulating typhoid fever but giving a negative Widal reaction as paratyphoid fever. But paratyphoid fever can only be differentiated from typhoid fever by the agglutination test of the blood serum, and by cultivation of the organism obtained through blood cultures. I have not seen an infection of this kind in St. Francis Hospital for the last seven years, a sign that it must be very rare.

Puerperal septicemia.—In this condition there is a high temperature with a quick, feeble pulse. The single fact that the patient has been confined a few days previously ought to lead the physician to doubt very strongly the existence of typhoid fever. In addition there is usually a wide daily range of temperature, profuse perspiration, and often great prostration.

SYRINGOMYELIA.

WITH REPORT OF A CASE OF MORVAN'S TYPE OF THE DISEASE.

By H. VALENTINE WILDMAN, JR., M.D.,

NEW YORK.

ATTENDING PHYSICIAN, CLEARING HOUSE FOR MENTAL DEFECTIVES AT THE NEW YORK POST-GRADUATE HOSPITAL.

Of all the diseases to which the nervous system is liable, the rarest and at the same time the most interesting is syringomyelia. The name was invented by D'Augers Ollivier in 1837, but he applied it to any cavity in the spinal cord, whether physiological or pathological. The association of a definite group of clinical symptoms with the cavity formation in the substance of the cord was first brought out by Schultze of Dorpatt and Kohler of Prague. Heretofore the disease had been undoubtedly confounded with amyotrophic lateral sclerosis, but with more careful observations the diagnosis of syringomyelia was made more and more frequently. Morvan's disease, which was originally described as a separate disease in 1883, has been now universally considered as a variety of syringomyelia, and there appear to be no grounds for classifying it as a separate morbid entity.

The disease is supposed to be more prevalent in Europe than in this country, but that may be due to the fact that cases are recognized there more frequently than they are here, although at best it is an uncommon disease. Males are more frequently affected than females, and the most usual time of onset is between ten and twenty-five years of age. The onset in the case here reported was at fourteen years. Heredity apparently plays no part in the etiology of this disease, but some congenital peculiarities are frequently present, especially changes in the skeleton, and some think that the occurrence of acromegaly, sometimes associated with syringomyelia, may be more than coincidence; but there is no definite information obtainable on that question as yet. Trauma is frequently mentioned in the anamnesia, as it is in many other diseases. It probably has nothing to do with its onset, and was absent in this case. Syphilis plays no direct part; whether it may do so indirectly is still an open question.

On examining the cord of a patient who has died from syringomyelia, the first thing noticed is the enlargement and flattening of the affected region, usually the cervical portion of the cord. The other parts of the spinal cord usually appear normal, and the membranes are clear unless there has been an

associated meningitis. One section of the cord is soft, and when in the region of the enlargement it may appear necrotic, with a cavity formation of varying size. The cavity is usually situated in the posterior gray commissure, posteriorly to the central canal of the cord, or in the base of the gray matter of either of the posterior horns. The cavities so formed are of neuroglial origin, the process being called gliomatosis, a term which separates it from the malignant tumors of the nervous system, and yet conveys the idea that it is formed of neuroglia, or the connective tissue of the nervous system. The actual mode of formation is still in doubt, but the theory most favored is that the material undergoes a sort of compression necrosis with softening and cavity formation as a result.

Douglas D.—Age 17, born in the United States. Father is a Canadian, aged 47, who has always been well. Mother was born in the United States, age 43, now dead from peritonitis. Patient had one brother six years older than himself who died of scarlet fever. There were no other brothers or sisters and none of his paternal or maternal relatives have ever had any nervous disease whatsoever. There are no insane, epileptic or tuberculous members of the family. His mother suffered no untoward accidents during the period of gestation. Patient was full term baby and birth was normal. Up to the age of fourteen years, patient was in all respects a normal boy always healthy.

When about fourteen years of age he first noticed that he was losing the strength of his right hand and that the muscles were getting thin and wasted. He could no longer throw a baseball nor hold objects as well as he could formerly. This trouble with his fingers progressed for a few weeks and then a flexion contracture developed. About this time he began to stoop very badly and it was for his round-shoulderedness that he first sought treatment, not paying much attention to the loss of power and atrophy of his right hand. He went to a well-known orthopedic hospital and was given a brace for his shoulders. This was about six months after the onset. The atrophy and loss of power which started in his right hand had now progressed to the arm and shoulder. The shoulder brace did no good and four months later he obtained another brace at a different hospital, but at neither place was any attention given to his underlying nervous condition.

About one year from the date of onset his left arm began to get weak but it became swollen and edematous, not wasted and atrophied like the right. The loss of power was however more complete in the left arm and the deltoid muscle almost completely paralyzed so that at the present time he can not raise his arm to the level of his shoulder. It was during this time that the patient noticed that the nails on his fingers were brittle and that ulceration was going on without there being any sense of pain. These painless whitlows became worse and he has since lost in succession the distal phalanges of his thumb and of the first and second fingers of his left hand. The nails on his right hand have been ulcerating at long intervals for the past three years and at the present time the beds of the neils are exposed on all the fingers of his right hand, yet he has no sensation of pain and in all probability whitlows will develop there as tney have previously done on the left hand. His appetite is good. Bowels are regular. He has no diminution or increase in sexual desire and has no sphincter troubles.

On physical examination we see a moderately well nourished boy with marked stoop due to weakness of shoulder and back muscles and a well developed scoliosis to the left. His face is rather expressionless and immobile, but not paralyzed. Eyes are normal in all respects. Teeth are poor. Tongue protrudes normally. Sensation of taste is normal. His lungs, heart, and abdominal viscera are normal. Skin and patellar reflexes are present. Station and gait are normal. His arms are abnormal. The right hand and arm are atrophied and the power of movement is very weak. The left hand has lost the distal phalanges from the thumb and first and second fingers and it is reddish, swollen, and slightly edematous. The shoulder muscles are paralyzed on the left side and the limb is practically useless. The testing of sensations is interesting. There is no dissociation of sensation but complete anesthesia over an area beginning from a line passing between the mastoid processes behind and from the notch in the thyroid cartilage to the mastoid processes in front, down to a line passing from the level of the third rib in front to the sixth dorsal spine behind and including both arms. This whole area is anesthetic to touch, pain, heat, and cold. The deep muscle sense is lost and the patient cannot tell in what position his hand is, nor can he place the other hand in a similar position. He can, however, touch the end of his nose with fair facility with the eyes closed. In his spine there is no evidence of bone disease nor of spina bifida either frank or occult.

The patient is perfectly happy and works around the ward on Randall's Island where he now is, until the development of his whitlows force him to desist. Just at present the disease seems to be quiescent, but the prognosis is of course very bad. He has received no medicine, there being none which has any effect on the disease and he not having had any symptoms to be relieved.

The case is interesting because of its rarity, because of the overlooking of the underlying trouble by two hospitals, and because of the unexplained etiology. At the present moment it looks as though the symptoms were caused by the pressure of the gliomatous material alone. Whether any dissociation of sensation will later develop is hard to say, but continued observation will be well worth while.

108 West Ninety-fourth Street.

RHINOLITH OF SEVERAL YEARS' DURATION IN A CHILD OF EIGHT.

By BARNET JOSEPH, M.D.,

NEW YORK.

FORMERLY RESIDENT PATHOLOGIST, KINGS COUNTY HOSPITAL, LATELY ASSISTANT TO THE CHAIRS OF PATHOLOGY AND ANATOMY, LONG ISLAND COLLEGE HOSPITAL, AND UNIVERSITY OF VERMONT, COLLEGE OF MEDICINE.

Rhinolith is a concretion in a nasal cavity. McFarland[1] claims that it is of common occurrence. The case herewith reported is the first I have observed in the examination of the nasal cavities of over a thousand patients and almost a like number of autopsies and dissections. From a perusal of the literature it is evident, however, that the condition is not infrequent.

S. R., eight years old, was one of a number of children who came for examination for admission to the Summer Camp of the Free Synagogue. She presented no abnormalities excepting slight asthmatic breathing in various regions of the left side of the chest. Keeping in mind that asthma in children is almost invariably the result of a nasal condition, I examined the nasal cavities and saw what I thought at first to be inspissated secretion in the upper half of the left nasal cavity. Attempts to remove it proved that, though movable, it was wedged between the turbinate and the septum, and that it was of stony hardness. Finding that the nares would admit a small artery clamp, I tried to crush the mass. Instead, however, it broke and came away in three parts. (See the illustration.)

The patient apparently had suffered no marked discomfort because of the concretion. The mother stated that the child was subject to colds almost all of the time and discharged mostly from one side of the nose. *The latter phenomenon, it should be remembered, is a characteristic of foreign body in the nasal cavities,* and in the case of children, or mentally defective adults, should especially attract attention.

The causative factor in this case appears to have been a fall on the face about five years ago. The child bled profusely from her nose for half an hour. The bleeding was checked, presumably by adrenalin.

The stone consisted of undefinable detritus, cal-

cium phosphate, carbonate, and hemosiderin. The latter constituent, found only in old, decomposed blood masses, proves that in this instance, at least, the nucleus was a blood clot. That a blood clot may be a responsible factor is vouched for by Moldenhauer, quoted by Felt.[2] In this connection it must be noted that a nucleus is not always found in a rhinolith.

It is remarkable to what size a rhinolith may grow. Thus Montague and Lake[3] obtained one weighing 48 grains; J. F. Hill[4] could not save all of the specimen from one case, but what he did weighed 275 grains; Botey[5] records the largest size—110 grams.

It stands to reason that the size of the concretion determines greatly the course and variety of symptoms. One of the principal effects of a stone of any size is a consequent atrophy of the mucous membrane. A reabsorption of the turbinates follows in time. In my case, there were marked granulations and the nasal cavity appeared abnormally widened.

FIG. 1.—Rhinolith, natural size.

Though the finding of foreign bodies is common enough in the nasal cavities of children, rhinolith is rather rare. Felt quotes a case of Ball's, of a child of four.

Though Handford[6] reports a case of foreign body in the nasal cavity for twenty-seven years, and Heberton[7] one of forty, it cannot for a moment be imagined that individuals so afflicted are in any sense comfortable. J. F. Hill's patient apparently suffered greatly for twenty-five years before he saw her and relieved the condition.

Only a minute need be spent in examining the nasal cavities of general patients, but the same may be the means of saving some of them much suffering from sinusitis, middle ear disease, chronic hoarseness, etc.

Tracheobronchial Adenopathy.—Francesco Amenta reports a case of asphyxiation in a child seven years old in which caseous tuberculous lymph nodes occluded the trachea. The clinical history had been the occurrence of repeated attacks of suffocation, of a violent cough without expectoration, of an intense general cyanosis, and of cold sweats. In cases of this nature the diagnosis from croup or from false croup is easy, but from a foreign body in the larynx the differential diagnosis is difficult. Attacks of pseudo-croup occur in the adenopathy of measles. In these cases the horizontal position of the patient seems to aggravate the attacks, whereas in tuberculous tracheobronchial adenopathy the vertical posture intensifies the attacks. —*Rivista Ospedaliera.*

Medicolegal Notes.

Privileged Communications—Purpose of Statute.—The object of the North Dakota statute prohibiting a physician being examined as a witness, without the consent of his patient, as to any information acquired in attending the patient, which was necessary to enable him to prescribe or act for the patient, is held to be to inspire confidence in the patient and encourage him to make a full disclosure to the physician of his symptoms and condition, by protecting against physicians making known to the curious the ailments of their patients, particularly when afflicted with diseases which might bring reproach, criticism, unfriendly comment, or disgrace upon the patient if known to exist. When a party to a litigation seeks to exclude the testimony of a physician on the ground that it is privileged, the burden is on such party to show that it is privileged. To make it privileged, two facts must combine, namely; the physician must have acquired the information while attending the patient in his professional capacity, and it must also have been necessary to enable him to prescribe or act for the patient. In an action for breach of promise of marriage, an offer was made to prove that the physician who attended the plaintiff during confinement, on a subsequent visit to her, was told by the plaintiff that she did not have intercourse with the defendant until about 6½ months prior to the birth of a child, that she never had any talk with the defendant about marriage, and that the reason she let him have intercourse with her was that she thought, if she became pregnant, he would marry her. It was held that, under the circumstances surrounding the visit, it was apparent that such information, if given the physician, was not necessary to enable him to prescribe or act for the plaintiff, and that therefore it was not privileged under the statute.—Booren v. McWilliams, North Dakota Supreme Court, 145 N. W. 410.

Negligence—Expert Evidence—Condition of Blood at Time of Injury.—In an action against a physician for negligence in setting a broken leg it was held that no one may expect as strong a leg after as before a fracture, and no physician or surgeon is held to a guaranty of results; but he is held to the exercise of the skill and learning of the profession generally in the community in which he practices. Whether he did that or not in a particular case may be proved either deductively or inductively, and the usual and customary treatment of physicians and surgeons in the particular locality may be shown in order to ascertain whether or not the defendant exercised the skill required of him.

It was also held that competent physicians and surgeons who have examined the result and learned of the treatment or knew what treatment should have been given, if assured of the patient's prior condition of health, and of his own care and treatment of the fracture, may properly give an opinion as to whether or not they found such results as usually follow from the customary treatment of such a case by men possessing the usual skill and learning of their profession in the locality where they practice. Such testimony must of necessity be admissible, for it may happen that the injured man is incapable himself of accurately describing the treatment given.

It was held admissible to show the condition of the plaintiff's blood at the time he was injured. He was not complaining of any infection, and blood troubles arise from infections of various sorts; but the evidence showed that the condition of the plaintiff's blood might have had something to do with the success of the treatment given him by the defendant. Every infection of a wound does not result in harm; to some extent this depends upon the condition and consistency of the blood, its normal or subnormal admixture of proper elements, and whether or not it has the usual powers of resistance within itself.—Baker v. Langan, Iowa Supreme Court, 145 N. W. 513.

X-Ray Photographs as Evidence.—In an action for personal injuries the physician who attended the plaintiff after his injuries, was present when an *x*-ray photograph of the injured limb was taken, saw the negative before it was delivered to the photographer to be developed, and identified the exhibit as the impression on the glass which he saw when it was taken. It was held that his testimony sufficiently proved the accuracy of the photograph to justify its admission in evidence, the physician having practised for 15 years, though without experience in taking *x*-ray photographs.—Prescott & N. W. R. Co. v. Franks, Arkansas Supreme Court, 163 S. W. 180.

CRANIAL MURMURS.

ALTHOUGH cranial murmurs have been recognized for a long time, particularly as indicative of intracranial aneurysm, the literature concerning them is very meager. Oppenheim, in his work on "Tumors of the Brain," calls attention to the frequency with which murmurs, rhythmical and synchronous with the pulse, may be heard over the cranium of individuals affected with some cerebral disorder. As the result of an experience comprising thirty cases, he concludes that this phenomenon indicates in most instances the presence of an aneurysm of the basal arteries of the cranium. Meyer has pointed out that the cranial murmurs are not constantly present in the case of intracranial aneurysms, nor are they always indicative of this condition. He has shown that the same sign may be produced by brain tumors, particularly if these compress a large blood vessel. Above all, the same observer has emphasized the fact that cranial murmurs can be detected in infancy before the closure of the anterior fontanelle without the presence of an intracranial affection. Rachitis, hydrocephalus, and anemia in older children may give rise to the same clinical sign. Severe anemia in adults is sometimes accompanied by the presence of a systolic murmur audible over the entire cranial vault. A congenital narrowness of the carotid foramen may be a cause of this phenomenon. Gowers has alluded to the presence of the latter in some cases of exophthalmic goiter and in cases of compression of the sympathetic nerve by tumors. D'Alloco reported a case of atheroma of the cerebral arteries in which a cranial murmur had been detected during life.

An important study of this subject has been made by H. Köster (Zeitschrift für klinische Medizin, Vol. 80, Nos. 5 and 6). He points out that in order that a cranial murmur may be detected the patient should be required to hold his breath. Prolonged and attentive auscultation is necessary. The phenomenon may disappear and reappear even during the course of the same examination. Its intensity is diminished or it may entirely vanish upon compression of the carotid. Sometimes the murmur has a whistling or musical sound. The material upon which Köster's study was based comprised sixty-six cases which are classified in the following groups: (1) Cases in which the murmur is associated with intracranial changes. (2) Cases without symptoms of disease of the brain, but with an anemia of high degree. (3) Cases with neither intracranial nor hemic changes. The general conclusions reached from an analysis of these cases are as follows: Cranial murmurs are present only in relatively rare instances of intracranial disease, and then have neither a general nor a local diagnostic importance, since the murmurs may arise with the most diverse changes in the cranium, irrespective of their localization. Of far more frequent occurrence are the cranial murmurs in the anemias of adults. These murmurs arise when the count of erythrocytes is less than 2,500,000 and the percentage of hemoglobin is less than 40. The percentage of hemoglobin appears to be of greater significance in relation to cranial murmurs than the reduction in the number of red blood cells. The anemic murmurs are heard loudest and sometimes exclusively in the parietal and temporal regions, and probably arise within the cranium, particularly in the carotid artery. In isolated instances in which neither intracranial disease nor severe anemia is present there may be heard cranial murmurs that are transmitted from the vessels of the neck. As an indiaction of the presence of intracranial disease a cranial murmur is of value only when the presence of a severe anemia can be ruled out. From the viewpoint of prognosis such murmur is of value in the case of a severe anemia, when the disappearance of the murmur indicates that the hemic condition has improved.

THE CHOICE OF A PRESERVATIVE FOR ANTIMENINGOCOCCUS SERUM.

WHEN one considers the site of injection and the amount of serum which is generally used in the treatment of cerebrospinal meningitis it must be admitted that the instances in which disagreeable symptoms appear are remarkably few. There have been offered two explanations for the development of collapse during, or shortly after the administration of serum in these patients. The obvious one that they are due to increase of intraspinal pressure because of a too rapid introduction of the serum is certainly true in a small percentage of cases, but Hale has shown (Hygienic Laboratory Bulletin, No. 91) that in the majority of instances the blood pressure falls abruptly, whereas it should rise if the intraspinal pressure had been unduly raised. He was able conclusively to demonstrate on dogs and cats that fatal symptoms accompanied by collapse and falling blood pressure resulted from the injection into the subarachnoid space of serum of solutions containing trikresol, the substance most generally used for the preservation of these sera. This substance, when introduced in close proximity to the vital centers seems to have a specific affinity for them and is able to bring about a fatal disturbance when given in exceedingly small doses.

More recently Voegtlin (Hygienic Laboratory Bulletin, No. 96, p. 87), working with dogs and monkeys, has been able to confirm Hale's work and

to extend it to other substances. He found that phenol produced a similar effect when used in a somewhat larger dose and that formaldehyde was even more toxic. Chloroform, however, whether in serum or in Locke's solution, caused a moderate rise in blood pressure even when the influence of the anesthetic (ether) was eliminated. This rise was followed by a slight fall and then a rapid recovery to the normal. In no instance were there any untoward symptoms, even though the dose was as high as 9 c.c. for a dog weighing 7.7 kilos. Chloroform is, of course, a perfectly satisfactory preservative from a bacteriological standpoint.

Voegtlin emphasizes the desirability of using gravity for the injection of such sera rather than a syringe, since with the latter it is extremely difficult to carry out the injection at a properly low pressure. The effect of the presence of choloroform on the antibodies contained in the antimeningococcus serum was not determined. The only objection mentioned is that a cloudiness develops in the serum on long standing due to a partial precipitation of the proteins, but it is claimed that this has no effect on the value of the serum. It would seem then that it would be advisable to discontinue the use of trikresol in such sera as are intended for intraspinous use. In its place chloroform might be substituted or the sera could safely be stored in sterile sealed glass ampoules.

TREATMENT OF BULLET WOUNDS OF THE ABDOMEN.

As a rule a bullet in traversing the abdomen causes multiple openings in the gastroenteric canal, and as a result of division of a number of small blood vessels, an effusion of blood mixed with the contents of the intestines takes place in the peritoneal cavity. If the amount is not excessive the effusion gradually sinks into the lesser pelvis. Laparotomy made as late as the second day after the injury may reveal an absence of blood in the abdominal cavity proper. The effusion in the lesser pelvis is usually infected through the admixture of intestinal contents, so that a pelvic abscess may often complicate the bullet wounds and their immediate sequelæ.

Professor Payr, the well-known surgeon of Leipzig University, now engaged in war activities, foresees the important role of these abscesses for the prognosis of small calibre bullet wounds of the abdomen. In an article in the new Military Supplement of the *Muenchener medizinische Wochenschrift*, August 18, he proposes measures to anticipate and deal with them. In recent wounds he would simply perform a minimum laparotomy above the symphysis, under local anesthesia, and insert a hard rubber drain into the lesser pelvis, thereby endeavoring to prevent the formation of an abscess. If, however, the patient is not seen until 48 hours have elapsed, he would first make sure of the existence of a pelvic abscess, and if one had formed would evacuate it through the rectum. Should this prove impracticable because of the absence of a circumscribed fluctuating mass beside the rectum, he would even make a parasacral opening with a view of draining the whole of the lesser pelvis. This step is justifiable because under the circumstances pelvic peritonitis often becomes generalized and fatal. The coccyx must be enucleated in order to secure the necessary drainage.

Payr does not discuss the treatment of the wounds themselves, but it is understood that in time of war this must be very largely conservative and expectant. Intestinal perforations sometimes close spontaneously. Laparotomies can seldom be performed in field hospitals, and in any case it is out of the question to deal with each unit directly in multiple injuries. The comparatively simple measures he advocates are believed to be able to prevent much mortality, but this can be decided only by the future.

VAGARIES OF MEASLES.

At a recent meeting of the Société Médicale des Hôpitaux, Garnier and Georges-Lévi Franckel (*Presse Médicale*, July 1, 1914) reported an epidemic of atypical measles affecting nine individuals. The disease was characterized by an incubation period of ten days, an invasion period of two to four days, and an eruption beginning either upon the face or upon the trunk, having a rapid evolution and terminating without desquamation. In two infants there was a complicating bronchopneumonia and in three adults there was an inflammatory arthritis. There was no adenopathy. By analogy with typhoid and paratyphoid fevers, the suggestion is made that one may speak of measles and of a so-called "fièvre paramorbilleuse (paramorbillous fever)."

The fact that some individuals are permanently immune to measles and that others enjoy a temporary immunity is commented upon by J. K. Friedjung (*Wiener medizinische Wochenschrift*, 1914, No. 18). The incubation period which has been definitely established by Panum as thirteen or fourteen days may however in some instances be as much as twenty-one days. The cause of this prolonged incubation period is attributed to an inherited relative immunity. The occurrence of secondary attacks or relapses of measles has not, in the opinion of this observer, been definitely established, and must, at any rate, be exceptionally uncommon.

The Study of Tropisms in Tissue Cultures.

The artificial cultivation of tissues has supplied a new field for the investigation of many biological problems. One of these is the nature of the influences that govern the direction of growth of any group of cells or any tissue. Thus it has long been recognized that the regenerating nerve fiber in growing out toward the periphery of the body is subjected to the influence of some tropism. Fischer demonstrated a chemotropism exerted in the case of proliferating epithelium when drops of oil tinted with scarlet red attracted toward them the growth of the epithelial cells. Eugenio Centanni (*Pathologica*, June 15, 1914) pursued various investigations along this line with interesting results. He studied the effect upon the direction of the artificial growth of tissues by bringing close to them capillary tubes containing other tissues or chemical substances. He found that when the growing tissue is in proximity

to another tissue from the same animal there is a positive tropism between the two. There is an exception, however, when the second tissue is obtained from the suprarenal gland, in which case there is exerted a negative tropism upon the first tissue; that is to say, the first tissue grows away from the suprarenal tissue. Solutions of suprarenal extract exert the same influence in this respect as the suprarenal gland itself. Drugs belonging to the nervine group, such as strychnine, caffeine, nicotine, morphine and chloral, appear to exercise a positive tropism on growing tissues, whose proliferation is stimulated in the direction of the chemical solution. This stimulating influence is most pronounced in the case of chloral.

Cancer Problems

It is often said that a disease which never undergoes spontaneous involution is beyond all therapeutic aid as far as a cure is concerned. If this were true the many recorded cases of spontaneous cure of cancer must then be explained by the therapeutic nihilists on the basis of a wrong diagnosis. At a recent meeting of the Berlin Surgical Society (*Berliner klinische Wochenschrift*, August 3), von Hansemann represented this pessimistic view. He even disputed the diagnosis of malignancy in those cancers of the face which yield to arsenic paste, for he said it is certain that arsenic cannot cure cancer. Bier, without actually gainsaying this viewpoint, cited numerous instances in which undoubtedly malignant growths responded decidedly to non-surgical measures. In one remarkable case injections of pig's blood caused striking clinical improvement in a cancer of the tonsil with regional lymph-node metastases. He was inclined to behold in a combination of radiotherapy with blood injections future possibilities of cure. Rotter reported a case of spontaneous cure of rectal cancer, confirmed by autopsy, at which another malignant growth was found in the greater pelvis.

Stretching of the Sciatic Nerve.

This method of treatment of sciatica, of which little has been heard within recent years, has been applied with good results in seven rebellious cases of this condition by Giulio Nannini (*La Riforma Medica*, July 25, 1914). By means of an incision on the posterior aspect of the thigh just below the buttock, and by the separation of the muscles, the nerve is exposed and isolated and is then subjected to firm traction in such manner that the entire length of the nerve responds to the mechanical stress. The traction should be continuous and not a series of sudden or violent jerks. During the first few days following the operation the patient experiences a vague pain, but this is less than before the operation; later there is a feeling of paresthesia in the distal part of the limb, a feeling as if this were about to fall off; still later all symptoms disappear and on the tenth to the twelfth day the patient begins to walk. The modus operandi of the stretching operation is difficult to explain. Of course the rupturing of adhesions is an important item. But the traction on the nerve causes vascular and nutritional changes in the parenchyma of the nerve and in the perineurium, which changes may be important factors in the cure.

Uremia as a Terminal Manifestation.

It has been shown by a number of clinicians that whatever the actual cause of chronic nephritis may be, it is nevertheless associated with a chronic and progressively increasing uremia. This condition has also been observed in acute mercurial anuria, and toward the lethal stage of such infections as pneumonia and typhoid fever. D. Dumitresco and A. Popesco, in the *Presse Médicale*, June 27, 1914, present the results of their observations which show that, in diseases which during their cause are not accompanied by an increased nitrogenous content of the blood, there is, as death approaches, an increase in the amount of urea in the blood, a condition which the above authors designate as a terminal uremia. This condition shows a more or less abrupt increase during the agonal period, and a less marked increase during the preagonal period. In cases of violent death occurring in the midst of health this terminal condition does not occur. There is a slight increase in the nitrogen in the blood during the first few hours after death—as it were, a post-mortem uremia.

News of the Week.

An Experiment in Health Administration.—Under the direction of the Health Commissioner of New York an area on the east side of the city, bounded by Scammel, Division and Clinton Streets, and the East River, has been marked off as a "health district," in which will be tested the value of a method of local health administration. This consists in the proposed government of the district, for health purposes, from within the district itself with the cooperation of a local volunteer health board, instead of from Department headquarters, and in the control of field workers by a local director in the place of various bureau chiefs. This plan aims at the avoidance of overlapping by different bureaus or departments concerned with health matters, and at increased usefulness through the establishment of intimate neighborly relations between the Department of Health and the local community. The development of the plan is under the control of Dr. Shipley.

Feeding the Prisoners.—The following is the daily ration given by the British War Office to its prisoners of war: Bread, 1½ pounds, or biscuits, 1 pound; fresh or cold storage meat, 8 ounces, or preserved meat, half ration; fresh vegetables, 8 ounces; butter or margarine, 1 ounce; condensed milk, 1-20th of 1-pound tin; tea, ½ ounce, or coffee, 1 ounce; sugar, 2 ounces; salt, ½ ounce. The German soldier who would be hungry on such a ration must have a Gargantuan appetite.

St. Luke's Day Service.—On the evening of Sunday, October 18, St. Luke's Day, there will be a special service for physicians and nurses at Calvary Church, Twenty-first street and Fourth avenue, New York. The rector, the Reverend Theodore Sedgwick, will conduct the service and addresses will be made by Drs. Howard A. Kelly of Baltimore and William H. Jeffries of St. Luke's Hospital, Shanghai.

Harvey Society.—The second lecture in the Harvey Society course will be delivered at the Academy of Medicine on Saturday evening, October 24, at 8:30 P.M. by Dr. Thomas Lewis of London. Subject: "The Excitatory Process in the Heart."

Minnesota State Medical Association.—At the annual meeting of this Association, held in St. Paul on October 1 and 2, the following officers were elected: *President*, Dr. John T. Rogers of St. Paul;

First Vice-President, Dr. L. M. Roberts of Little Falls; *Second Vice-President*, Dr. E. S. Muir of Winona; *Secretary*, Dr. Thomas McDavitt of St. Paul; *Treasurer*, Dr. Earle R. Hare of Minneapolis.

Removals.—Dr. B. Michailovsky has removed to 235 West Seventy-first street, west of Broadway.

Dr. Bruno S. Horowicz has removed to 448 Central Park West, corner of One Hundred and Fifth street.

Cornell University Medical College opened on Wednesday, September 30, 1914, with an enrollment as follows: For the degree of M.D. first year, 55; second year, 28; third year, 32; fourth year, 20; special students (work not leading to the degree of M.D.), 12; for the degree of Ph.D., 5; making a total of 152. All students now registered, with the exception of those pursuing the combined seven years' course leading to the degrees of A.B. and M.D., are graduates of Arts and Science, or Doctors of Medicine doing advanced work. Students in the combined course present the baccalaureate degree before they are admitted to the second year in medicine.

The Efficiency of the Eye Under Different Conditions of Lighting.—On Monday evening, October 19, at the Museum of Natural History, Seventy-seventh street and Central Park West, Professor C. E. Ferree of Bryn Mawr College, will deliver a lecture on the above subject before the Section on Astronomy, Physics, and Chemistry.

Obituary Notes.—Dr. Thomas Opie, one of the founders of the College of Physicians and Surgeons of Baltimore, and dean of the institution from 1872 to 1905, died at the home of his daughter in Washington, D. C., on October 6, aged 72 years. Dr. Opie was born in Martinsburg, Va., and was educated at the University of Virginia and the University of Pennsylvania, receiving his medical degree from the latter in 1861. During the Civil War he served in the Confederate Army, first as a private and later as a surgeon in the Twenty-fifth Virginia. After the war he practised in Baltimore, and was for many years professor of obstetrics at the College of Physicians and Surgeons and sugeon to the Baltimore and Bayview Hospitals. He was a member of the American Medical Association and the Medical and Chirurgical Faculty of Maryland, and one of the charter members of the American Association of Obstetricians and Gynecologists.

Dr. Raymond B. Coonley of Detroit died in that city on September 19, at the age of 25 years. He was a graduate of the Medical Department of the University of Michigan in the class of 1913.

Dr. Benjamin F. Wyman of Kitchings Mill, S. C., a graduate of the Medical College of the State of South Carolina, Charleston, in 1869, and a member of the South Carolina Medical Association and the Aiken County Medical Society, died at his home, from pneumonia, after a short illness, on September 30, aged 74 years.

Dr. Herbert E. Bennett of Mentone, Ind., a graduate of the Starling Medical College, Columbus, O., in 1879, died suddenly from heart disease, on September 27, aged 50 years.

Dr. Harry D. Belt of Chicago, Ill., a graduate of the Medical College of Ohio, Cincinnati, in 1897, and a member of the Illinois State and Chicago Medical Societies, died at his home, after a short illness, on September 29, aged 40 years.

Dr. William Henry Downey of Taunton, Mass., a graduate of the Harvard University Medical School, Boston, in 1898, and a member of the Massachusetts and Bristol North District Medical Societies, died at his home on October 1, aged 49 years.

Dr. Alonzo M. W. Westfall of Prairie City, Ill., died at his home on September 28, from acute dilatation of the heart, at the age of 70 years.

Obituary.

WASHINGTON EMIL FISCHEL, M.D.

ST. LOUIS, MO.

Dr. Washington Emil Fischel died in St. Louis September 15, 1914. Although a great sufferer during the last months of his life, and knowing that the end was not far off, such was his courage and powers of endurance, that few of his associates and friends knew of his condition until a short time before his death. Dr. Fischel was born in St. Louis, May 19, 1850, and received his degree of M.D. from the St. Louis Medical College in 1871, and subsequent degrees from the universities of Prague, Vienna, and Berlin, after which he returned to his native city, and began a general practice of medicine in 1874. His exceptional ability being soon recognized, he was invited to fill a chair in the St. Louis Medical College, and from that time he became an important factor in everything concerning the college.

In the making of the St. Louis Medical College into a self-governing adjunct to Washington University, in the joining together of the St. Louis and the Missouri Medical Colleges, and in the final merging of these united colleges into Washington University as the Washington University Medical School, Dr. Fischel played a very important part. Later, when it was thought advisable to reorganize this school, he was again an active and wise assistant in the work to be done in filling the many vacancies that ensued in the school. After this reorganization, Dr. Fischel continued to serve the college as clinical professor until his death.

When the Barnard Free Skin and Cancer Hospital was built, through the generosity of one public-spirited citizen, and it became necessary to interest the public in its maintenance, Dr. Fischel's popularity and influence were material aids in the very successful results obtained. He continued to be a useful member of the staff of this hospital until he died.

During his long and successful career in St. Louis, Dr. Fischel filled many honorable positions in the medical world, and was a member of many societies for the promotion of medical and other sciences, as well as those for purely social purposes. Burdened with a large practice, and with seemingly so little time for his own diversion, he never neglected his social duties, and was never happier than when surrounded by his family and friends, and was always the life of any party of which he was a member.

In the passing away of Dr. Fischel the community in which he lived has sustained a loss that will be greatly felt. His attainments in his profession and his work for civic good won for him the respect of all, and his kindly disposition and the deep, affectionate interest which he displayed towards those for whose well being he was working gained for him a place in their hearts that will be hard to fill. As a friend, as a successful physician, and as a good citizen, for Dr. Fischel was all of these, he will be greatly missed.

N. B. Carson, M.D.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

WAR ITEMS—THE SELECT COMMITTEE ON SECRET AND PROPRIETARY MEDICINES — FURTHER REPORT — OBITUARY.

LONDON, September 24, 1914.

THE war is the uppermost subject with every one you meet in the most casual way. The many hospital beds set apart for the wounded have so far provided for the arrivals. From some hospitals many of the resident staff have proceeded on active service. So have a considerable number of men in private practice who have been able to arrange for friends or assistants to carry on work during their absence. The payment is sufficient to secure from loss those with a limited clientele, but some long-established practitioners will no doubt make a sacrifice by going to the front. The medical corps has also its "roll of honor" in the list of casualties, already too long to repeat it here. The work of the Red Cross has in several instances been insufficient to protect those engaged in the work of mercy from injury or death at the hands of some German soldiers. It is to be hoped, however, that these will prove to be exceptional.

At Louvain we have the opposite picture—Dr. Noyous and his wife staying in the town to look after the wounded who could not be removed when the order was issued for everyone to leave before the further bombardment. A leaflet has been issued giving explicit instructions for the prevention and treatment of sore feet, which if only followed by the troops will save them much suffering.

Mr. G. H. Makins, C.B., surgeon to St. Thomas' Hospital, has joined the staff of the P. M. O. of the Expeditionary Force as the consulting surgeon.

The dependents of the men at the front are being looked after. A committee of the medical, the pharmaceutical, and the health insurance societies having been formed to provide them with medical and other relief. The Prince of Wales' Fund will defray the cost of the scheme.

Continuing my account of the Report of the Select Committee on Secret Remedies I should tell you that some distinction is made as to so-called medicated wines, of which large quantities are sold. They undoubtedly lead in many cases to intemperate habits, and it is well that the committee recommends that any proprietary remedy containing more alcohol than the amount necessitated for pharmacological purposes should show on the label the proportion present.

Passing by the articles which are classed as (*a*) genuine scientific preparations, and (*b*) unobjectionable remedies for simple ailments, there are, it is said, many secret remedies making grossly exaggerated claims of efficacy; causing injury by leading sick persons to delay in securing medical treatment; containing in disguise large proportions of alcohol; sold for improper purposes; professing to cure diseases incurable by medication, or essentially and deliberately fraudulent. This last class (*c*), the character of which is thus explicitly stated, the committee declares contains none which spring from therapeutical or medical knowledge, but they are put on the market by ignorant persons, and in many cases by cunning swindlers, who exploit for their own profit the apparently invincible credulity of the public. This they add constitutes a grave and widespread public evil.

The next point in connection with this exposure of the traffic is that in other countries and in some of our Dominions there are severe legal restrictions and a tendency to still further strengthen law against these articles. But in this country there is no officer and no department charged with the duty of controlling this trade, though it is possible the public prosecutor has not sufficiently tested the powers of the existing law in respect to such cases—consequently the traffic in quack medicines is practically uncontrolled, an intollerable state of things urgently demanding new legislation for the protection of the public. In what directions? After such a full exposure of an extensive evil it might be supposed the committee would recommend a drastic procedure. They are evidently impressed with the important part that the pretended secrecy of these medicines plays in deceiving the public. Yet they are not prepared to require the formula of every alleged remedy to be shown on the label. Nevertheless, they say it is improper that under the protection of the law enormous quantities of alleged remedies should be sold, the composition of which is unknown to any person except the manufacturers of them.

Therefore, they recommend that the formulæ of all secret remedies should be required to be communicated to a competent officer appointed under the authority of a minister of state. So far, good—that would be at any rate a sort of half-way house to the end they seem to think desirable. What is more hopeful still is that they would have the administration of the law governing the advertisement and sale of all secret and proprietary remedies combined under the authority of one department of state—this department to be that of the Minister of Public Health, "when such a department is created." Thus they adopt as practically sure to be carried the proposal for such a minister to be appointed, which has for years been the measure demanded by a very large number of ardent reformers.

An octogenarian doctor, retired long since, says that when he began to study for the profession, more than half a century ago, the demand for the appointment of a Minister of Health was most popular, and in many directions an early compliance with this desire was expected. Now that the idea is endorsed by a parliamentary committee there should be some hope of its realization, but it will demand determination from a strong government to accomplish it; for although non-political acts often pass easily enough on the recommendation of a select committee, if they do not touch the pockets of any section, this proposal is certain to excite the most intense opposition from those who are deriving enormous incomes from the sale of these quack medicines and to whom the committee has applied the terms of "ignorant persons" and "cunning swindlers."

Sir Henry Greenway Howse, consulting surgeon to Guy's Hospital, died on the 15th inst. in his seventy-third year. After taking the curriculum at Guy's, he passed the M.R.C.S. in 1865 and proceeded to the fellowship in 1868, taking the M.S., London, the same year. He was president of the college 1901-3 and a member of the senate of the university 1900.

Dr. A. Wigglesworth, who was on the surgical staff of the Irregular Cavalry in the Crimea, died August 24, aged eighty.

2. X-Ray Evidence in Early and Latent Cancer of the Stomach.—By F. W. White and R. D. Leonard. (See MEDICAL RECORD, June 6, 1914, page 1051.)

3. Traumatic Endocarditis.—S. G. Webber states that the severer lesions caused by external violence, as rupture of heart or pericardium, and the rupture or tearing of valves, give rise to symptoms which are recognized very soon or immediately after the accident and are generally fatal at once or after a comparatively short time. They are easily diagnosed, and reports of many such cases are found in medical literature. Less severe injuries may give rise to slight lacerations of the cardiac muscle or to ecchymoses into its substance or just beneath the endocardium which cause only temporary inconvenience, the symptoms thus produced soon disappearing. These slighter injuries may, however, give rise to changes in the valves which develop slowly and can be recognized only after the lapse of a longer or shorter time. These slight injuries have often been overlooked or entirely ignored as causes of valvular disease, the cardiac changes being ascribed to other causes. Several cases have been reported in which the early cardiac symptoms have been absent or of short duration and have seemed insignificant. After an interval of apparently restored health, valvular changes have developed, with their usual consequences.

5. Lung Abscess.—C. L. Scudder reports the details of a series of sixteen cases of lung abscess treated by operation. The following facts seem to the author to be apparent from a study of this group: The bronchiectatic process should be attacked by the surgeon while it is limited to one lobe of a lung. Actinomycosis of the lung must be recognized in its initial stage and vigorously attacked by surgery, for only in this way is there any likelihood of curing this fatal disease. Attention is directed to lung abscess following tonsillectomy. The surgeon should be alert to the occurrence of lung abscess associated with embolism following ordinary surgical operations. An increasing number of intraabdominal infections are associated directly with an infection through the diaphragm of the diaphragmatic pleura, and then of the lung with pulmonary abscess. These cases of subdiaphragmatic origin must be attacked early to prevent subsequent damage intrathoracically. The *x*-ray is of great value in the diagnosis of lung abscess. The author believes that this series of cases demonstrates the efficacy of surgical measures in the treatment of abscess of the lung. There were nine deaths and eighteen recoveries, and eleven cases were practically well without cough or sputum.

6. The Behavior of Neosalvarsan.—W. J. McGurn after an extensive experience with neosalvarsan is convinced that when accurately handled it is both safe and dependable; that in preparing and administering this agent a cool room with perfect illumination is of equal importance with strict asepsis; that the beginning of oxidation of neosalvarsan is simultaneous with its exposure to air, that "immediate injection" should be interpreted as forbidding a delay of more than ten minutes from the time of opening the ampoule until the injection is completed, which time can easily be reduced by half; also, that the use of therapeutic agents containing ammonium carbonate or mercury should be withheld or suspended for a period of forty-eight hours preceding and for several days following the intravenous administration of either new or old salvarsan.

2. The Medical Treatment of Intestinal Stasis.—By R. W. Wilcox. (See MEDICAL RECORD, September 5, 1914, page 440.)

3. Diagnosis and Treatment of Paresis.—H. W. Mitchell concludes that the hitherto so-called parasyphilitic diseases of the nervous system are now known to be late specific lesions due to the presence of *Treponema pallidum* in the tissues affected. The parasyphilitic conception is no longer tenable. A small percentage of syphilitics, for reasons not clearly understood, manifest types of cerebrospinal syphilis which have always been specially resistant to any known treatment. Thorough and intensive treatment, aiming to destroy the last spirochete in the early stages of the disease, affords the best known prevention. The efficacy of early treatment can be determined only by the use of laboratory methods which should be employed with all syphilitics. Relative accuracy in treatment can thus be substituted for doubt and guess work. The study of the cerebrospinal fluid is imperatively demanded in the diagnosis of syphilis of the nervous system. Intraspinous treatment offers some hope of checking the disease, and is the only route by which spirocheticidal agents can be brought directly in contact with the tissues bathed by the cerebrospinal fluid. More general application of this measure and longer observation of cases thus treated are needed for the final estimation of its therapeutic value.

4. The Prognosis in Acute Appendicitis.—E. M. Stanton states that the following conclusions regarding the prognosis of the disease are now generally accepted by most surgeons: (1) The mortality in cases operated upon during the first twenty-four to thirty-six hours of the attack is almost nil. (2) Cases without peritoneal involvement localized to the immediate vicinity of the appendix can be operated upon with safety at any period of the attack, provided they are in the hands of a competent surgeon. (3) Cases with early peritonitis of greater or less extent are best treated according to the method of Murphy, but like all other forms of peritonitis the mortality in appendicular peritonitis, even when treated by the Murphy method, rises rapidly in cases operated upon after the first day of the peritoneal involvement. (4) Late abscess cases should be drained, with or without the removal of the appendix, according to the exigencies of the case and the skill of the operator. The mortality in this class of cases should not be over 5 or 6 per cent. at the highest. (5) The bulk of the operative

mortality today is encountered in the severe cases operated upon during the intermediate stage of the attack, at a period when there is well-marked peritoneal infection of more than twenty-four hours' duration.

8. **The Abderhalden Test in Cancer.**—I. Levin has applied Abderhalden's method in the diagnosis of thirteen cases of carcinoma. Of these twelve were positive and one negative. Four sarcoma cases were all positive. Of twelve tuberculous cases five were positive and seven negative, and of a series of cases of light nervous ailments four were positive and four negative. The analysis of the results shows that while the test is most frequently positive in carcinoma it cannot be considered actually specific, since the same ferments seem to appear in the serum of noncarcinomatous individuals. The real difficulty lies in the complexity of the phenomena involved in the problem. Carcinoma tissue used for the test consists of cancer cells, connective tissue, and bloodvessels, and consequently must contain different protein substances, some of which may possess characteristics of carcinoma tissue, while other may be analogous to normal tissue. The serum, on the other hand, may contain a variety of specific and nonspecific ferments. All these may combine to give a positive ninhydrin reaction. It is imperative that a great deal more research, both clinical and experimental, be done before a decision can be reached as to the applicability of the test for the clinic. The protein substance which the ferments split up must be made to be more clearly specific and the test itself must be finer and not depend on the behavior of the dialyzer. All these matters are the subject of further research by the writer. But for the present the method belongs to the research laboratory and not to the clinic.

1. **The Modern Warfare Against Tuberculosis.**—S. A. Knopf pleads that those afflicted with tuberculosis, socially so situated as to be unable to secure the sanatorium treatment at home, be placed in institutions where with the aid of modern phthisiotherapy health and earning capacity may be restored. There should be no uncared-for tuberculous individuals. There should be an increase in the number of sanatoria, special hospitals, preventoria, home sanatoria, seaside hospitals for tuberculous joint diseases, etc. There should be a universal obligatory examination and reexamination of all citizens for the discovery of tuberculosis and other diseases; judicious cattle laws to prevent infection of the human race from cattle; proper housing laws and the supervision of factories and workshops to make dangerous infection impossible; reasonable and judicious temperance laws and rational antialcoholic educational movements; the abolition of child labor and the support of indigent pregnant women a few weeks before childbirth and partly during the nursing period; open-air schools in abundance and equally great attention demanded for the physique as for the brain in primary schools as well as in high schools and colleges; the thorough training of medical men in early diagnosis and special antituberculosis work and a just remuneration for the services they render thereby to the community; special training for nurses and social workers among the tuberculous; education in schools and colleges, factories and workshops, by literature and lectures, exhibits and museums in all that pertains to the prevention of tuberculosis; the furtherance of sanitary living and the avoidance of infection from other diseases. Statesmen should make laws which will render farming more profitable, so as to attract fewer people to the cities and more to the country, and there should be state, provincial, and municipal labor bureaus to adjust the supply to the demand for labor in various localities. Last, but not least, there should be a readjustment of the earnings of the laboring men; there should be a minimum wage which will enable each individual, if he works, to earn enough to live, eat, and clothe himself decently. There must be no underfeeding, no bad housing, more enlightenment, and more sanitary education. Tuberculosis, in order to cease to be a disease of the masses, must no longer be a disease of ignorance, congestion, or underfeeding; in other words, in order that one may combat the great white plague there should be more social justice, more humanity to the unfortunate, more kindness and love for those so sorely in need of it. The war should be against tuberculosis, but never against the tuberculous.

2. **Nonoperative Treatment of Tuberculous Glands of the Neck.**—By R. T. Morris. (See MEDICAL RECORD, September 5, 1914, page 437.)

3. **The Effect on Blood Pressure of Decapsulation of the Kidney.**—E. H. Goodman reports the case of a patient with advanced renal disease in whom a remarkable fall in blood pressure followed a decapsulation operation. Before operation the systolic pressure was fairly high, but the diastolic pressure was unusually elevated, indicating an extraordinary increase of peripheral resistance. After operation both pressures fell—the systolic to normal, and the diastolic pressure to approximately normal, though one day it was as high as 110 mm. Hg. Subjectively the patient was much benefited, and the improvement was so marked that he became, for the first time, hopeful of his ultimate recovery. The edema was less; there was less dyspnea, and the urine was slightly increased in amount.

4. **Postdiphtheritic Paralysis.**—W. M. Barton states that recent experimental and pathological investigations have apparently remonstrated that the diphtheritic process affects the lower neuron throughout its entire extent, including the radicular cell and the peripheral nerve fiber. It is somewhat difficult at the present time to say exactly what portion of the phenomena observed are to be referred to the centrally, and what to the peripherally localized lesions. The alterations in the peripheral portion of the neuron are usually regarded as the most important. The treatment of diphtheritic paralysis with large doses of antitoxin has been advocated in France since 1896. Combe, in particular, is an ardent exponent of the treatment. He believes that every case of diphtheritic paralysis, recent or old, localized or general, should be treated with antitoxin.

6. **Acute Intestinal Obstruction.**—H. M. Armitage states that the three symptoms of importance in this condition are pain, constipation, and vomiting. When the fecal current alone is interfered with the pain is colicky. If strangulation is present the pain is violent and the patient is shocked. Lavage of the stomach and a well-given enema do not relieve the pain. There is generally a history of constipation and also of attempts to move the bowels by the use of cathartics. There may be a history of constipation following a diarrhea. When the fecal current alone is interfered with, violent peristalsis ensues, and if the abdominal wall is not too thick

this will be visible. Visible peristalsis is not as valuable a sign of complete intestinal occlusion as stiffening of the bowel wall, which may be felt upon palpation. The vomiting is persistent. At first it is reflex, but later mechanical. It is not controlled by lavage. Hiccough may be present instead of vomiting. One should operate in those cases in which the patient is not relieved and every effort to secure the passage of gas and feces results negatively. In those cases in which lead poisoning and gastric crisis are proved to be absent, but in which there is no permanent relief from pain, and in which the constitutional symptoms of shock progress, one should operate, although the bowels move slightly and gas passes, because these are cases of incomplete obstruction and a certain percentage become complete. If they remain incomplete, operation offers the best chances for recovery, since even these cases may present the secondary symptoms of toxemia, and death may ensue without the bowel becoming wholly occluded.

7. **Expert Testimony from the Standpoint of a Lawyer.**—A. M. Holding states that the opinion of a medical man is admissible in court with respect to the condition, physical or mental, of a certain individual; the cause of death or of disease; the cause of an injury; the effect of an injury; the effect of a drug or a particular treatment; and the probability of recovery; or with respect to questions perculiarly within the knowledge of the expert. The opinion of a medical expert may be based either on observation or on personal examination or on a hypothetical case stated in court. It must not be based upon mere hearsay or information gained from the statements of others obtained out of court. The expert must not base his opinions upon the voluntary statements of the patient as to his symptoms and the condition of his health, nor upon an examination made at the patient's request for the purpose of securing testimony in the patient's behalf; nor upon the description of the patient's condition given by third parties; nor upon information derived from private conversations with other physicians or experts. The opinions of medical experts are not admissible upon any of the following subjects: (1) Matters that do not come within the province of the physician's skill, for instance, as to what caused certain marks on the throat of the deceased, or as to the position of A when he shot B; questions of law; conclusions or inferences which it is the province of the jury themselves to draw, or matters of mere speculation.

2. **Aperiosteal Amputation.**—By H. H. M. Lyle. (See MEDICAL RECORD, June 27, 1914, page 1194.)

3. **Sporotrichosis in the Mississippi Basin.**—R. L. Sutton concludes that cutaneous sporotrichosis is a comparatively common disorder in the Middle West. In every suspected case a bacteriological test should be made as early as possible, otherwise the employment of powerful antiseptics, such as iodine, may render cultural examinations negative even though the fungus is still present. In the majority of instances the symptomatology of the affection is so characteristic that a mistake in diagnosis is hardly possible if one is at all familiar with the disease.

4. **Bilateral Peripheral Facial Palsy.**—T. B. Throckmorton states that bilateral facial paralysis is much more rare than is the unilateral type. While exposure to cold, drafts, localized congestive conditions, infectious and toxic processes, etc., seem to be largely responsible as direct agents in the production of the peripheral type of facial paralysis, the relationship between the nerve-trunk and its bony canal (Fallopian aqueduct) may not be altogether a negligible factor. Congenital narrowing or stenosis of the Fallopian aqueduct may be more instrumental as a true basic causal factor in the production of peripheral facial palsy than is commonly believed. Hereditary predisposition to peripheral facial paralysis may be present in some individuals.

6. **Pemphigoid of the Newborn (Pemphigus Neonatorum).**—H. N. Cole and H. O. Ruh present the following summary of their study of this subject: In an epidemic of nine cases of infantile pemphigoid (pemphigus neonatorum) it was possible to isolate in pure culture the *Staphylococcus aureus* in all cases in which unbroken vesicles were to be found. In one case the termination was fatal and a coccus was found in the internal organs at necropsy. The epidemic was started from a case of typical pemphigoid of the newborn, which later changed into a clinical picture of dermatitis exfoliativa neonatorum, and as the etiological agent in both diseases is the same the authors believe there should be no distinction between them. Impetigo contagiosa seu vulgaris seu bullosa (streptogenes) should be sharply differentiated from infantile pemphigoid because of its different bacteriological origin. The authors believe that infantile pemphigoid should be placed among the reportable diseases because of its severe epidemic characteristics and high mortality (from 25 to 50 per cent.). Because of the striking results obtained in the authors' epidemic they would recommend the use of an autogenous vaccine in alll cases of infantile pemphigoid.

12. **Feeding of Skimmed Breast-Milk.**—By F. C. Neff. (See MEDICAL RECORD, June 27, 1914, page 1195.)

14. **Autoserum Treatment in Dermatology.**—W. S. Gottheil and D. L. Satenstein report their results with this method of treatment in eighteen cases including twelve of psoriasis, two of radiodermatitis, and one each of furunculosis, pustular acne and dermic abscesses, chronic urticaria, and lichen planus. The case

of pustular acne has been very markedly improved, is still under treatment, and is nearly cured; and the cases of urticaria, lichen planus and furunculosis have greatly improved. One of the radiodermatitis cases was a gangrenous one, and the result is characterized as astounding. The patient was apparently in a hopeless condition, was constantly under opiates, and could hardly get out of bed, and the sloughing ulceration had been almost unaffected by the various local and general measures that had been tried. The result of even the first injection was the rapid throwing off of the necrotic tissue, a beginning cicatrization of the ulceration, a cessation of the agonizing pain and the tenderness, and a rapid convalescence. This was a patient who had the symptoms of serum sickness after his fourth injection; the treatment was stopped in consequence of it; at present the patient is perfectly well and attending to his business; the ulceration is three-quarters healed, healthy, and slowly closing up under ordinary surgical local treatment. These patients were given from four to six autoserum injections at intervals of from five days to one week, during which time they were not hospital patients or confined to bed, but could pursue their ordinary avocations.

6. The Sterilization of Potable Waters by Means of Calcium Hypochlorite. J. C. Thresh.

1. **Dysentery.**—F. M. Sandwith devotes his third lecture on this subject to bacillary dysentery. He states that this type of the disease is met with in all parts of the world, particularly in times of war and famine and in crowded institutions, such as lunatic asylums and prisons. Several varieties of the causative bacilli have been described, differing from each other in detail and particularly in their action upon sugars. The varieties are usually divided into two types: the Shiga-Kruse, which does not ferment mannite, and the Flexner or mannite-fermenting type. To these two types must be added the *Bacillus dysenteriens El Tor*, desbribed by Ruffer in 1909 and found then and since to be the chief cause of dysentery among pilgrims returning from Mecca to the quarantine station at El Tor on the Red Sea coast. The Shiga bacillus is the commonest cause of bacillary dysentery. The incubation period is short—from one to two days. The onset is usually sudden, but may begin with one or two days of diarrhea. Griping pain in the colon is the first symptom, followed very shortly by motions which consist only of a little blood and mucus. The tenesmus is so constant that the patient is hardly content to be away from the bed pan. The fever from an uncomplicated case is seldom above 101° or 102° F., and does not last for more than three to eight days, while in a mild case the temperature may never be above 99°. The stools may vary in the twenty-four hours from twelve to fifty or many more. The tongue is slightly coated or may be clean, but there is no appetite for food. A fatal case gradually develops a rapid pulse, cardiac failure, and collapse, in spite of an apparent improvement in the temperature and in the frequency and appearance of the motions. In gangrenous or fulminating cases the symptoms are severe from the onset, the stools may resemble washings from raw meat, with large sloughs of necrosed mucous membrane, causing death as early as the third or fourth day. The group of symptoms called dysentery in tropical and subtropical parts of the British Empire is usually labeled ulcerative colitis in the United Kingdom, at least outside lunatic asylums. One is confronted by an illogical outcome, for a case diagnosed as ulcerative colitis in a London hospital ward might be relabeled if it were discovered later that the patient had lived in the tropics and that his feces contained amebæ or bacilli; or, again, if he became insane and had a colitis relapse in an institution the complaint would be called "asylum dysentery." The author draws attention to the extraordinary and unexplained prevalence of bacillary dysentery among lunatics. It seems to linger in some asylums as if it were the last remnant of the dysentery which used to be so prevalent in Great Britain. Shiga says of bacillary dysentery: "Always a constant companion of war it has been more fatal to armies than powder and shot."

4. **The Composition and Derivatives of Urinary Dextrin.**—P. J. Cammidge and H. A. H. Howard report the discovery of a process by which the dextrin in a urine can be estimated even in the presence of sugars if free pentoses have been excluded by preliminary tests. This process has enabled the authors to investigate the occurrence of this body in diabetes and other pathological conditions and also to watch the variations that occur in different circumstances. The process is not sufficiently delicate to detect the trace of dextrin present in normal urines, and it is found that the urine of healthy individuals has an iodine coefficient of nought. When carbohydrate metabolism is being imperfectly carried out a high iodine coefficient is obtained. If, however, the interference with carbohydrate metabolism is such that sugar appears in the urine, a previously high iodine coefficient usually falls, to rise again when the sugar disappears. In many cases of persistent glycosuria, too, this movement of the iodine coefficient and the sugar excretion in opposite directions has been observed, a rise in the one being accompanied or preceded by a fall in the other. In severe cases of diabetes, where more sugar is being excreted in the urine than would be accounted for by the carbohydrate taken as such in the food, particularly when a fatal termination is close at hand, the course of the iodine coefficient of the urine and sugar excreted follow each other. These observations suggest that the urinary dextrin is probably a derivative or antecedent of glycogen, intermediate between that substance and dextrose. In the former case the body still possesses the power of breaking down glycogen to a polysaccharide of low molecular weight, but this, instead of being converted into dextrose, which in its turn would give rise to CO_2 and H_2O, suffers irregular oxidation. It is also possible that the urinary dextrin may result from an incapacity on the part of the tissues to form glycogen from dextrose, the process stopping short at the intermediate dextrin stage. In support of this view there is the fact that in mild and intermittent cases of glycosuria the iodine coefficient of the urine vanishes on a carbohydrate-free diet to reappear again when dextrose is added to the food in insufficient amount to bring about a return of the glycosuria, suggesting that when the glycogen stores of the body have been reduced by the exclusion of carbohydrate from the diet the tissues recover to a certain extent their powers of building dextrose into a more complex molecule, but cannot carry all of it beyond the dextrin stage. It has also been found in cases of hepatic disease in which dextrose can be utilized but in which levulose and lactose give rise to alimentary glycosuria, that the ingestion of dextrose is not associated with an in-

crease in the iodine coefficient of the urine. When, however, either of the other sugars is given in sufficient amount the iodine coefficient rises, suggesting that dextrose can be converted into glycogen, but that part of the levulose and lactose can be carried only to the dextrin stage, some being excreted in an even less completely metabolized condition.

9. The Babinski Sign in Transient Functional Diseases. F. C. Eve.

1. Toxemic Iritis.—W. M. Beaumont refers to the frequency with which iritis is associated with arthritis, or at least with arthritic pains. It is noteworthy, too, that the arthritic and iritic symptoms are often so accurately coadjusted that exacerbations in the eye and joint frequently recur synchronously. On the other hand, practically never is acute rheumatism coincident with iritis. In the dyscrasia of syphilis and in that of gonorrhea a source of infection is clear and unmistakable. In traumatic iritis, due to a perforating wound, germs obtain direct access to the iris, and even in operating under the strictest asepsis the surgeon's path of incision may become the road of sepsis. Possibly, too, in sympathetic ophthalmitis toxins are elaborated in the exciting eye which have a specific affinity for the iris and other structures of the sympathizing eye. There is an ill-defined type of iritis arising from a dislocated lens in which there is apparently no path of entry for organisms from without. It is noteworthy that the iritis in such cases shows few signs of inflammation, although there are discoloration of the iris and posterior synechiæ. Such a low form of infection is probably caused by organisms of attenuated virulence. In diabetes the marked tendency to the dermic formation of boils and carbuncles of obviously infective nature may possibly explain the source of iritis, but on the other hand they may be the coeffects with the iritis of a common infection. Iritis, although credited to malaria, is a rare complication in paludal disease, while that which sometimes follows late in cases of herpes of the fifth nerve would seem to be undoubtedly of infective origin. The author has seen iritis in association with adiposis dolorosa, but as the patient suffered at the same time from dental sepsis it was probable that the latter was a factor common to both, inasmuch as adiposis dolorosa is due to an inflammation of the fibrous tissue of the panniculus adiposus. Except in sympathetic ophthalmia the iris does not appear to be readily accessible to microbic invasion following injuries of distant parts of the body. Pyorrhea alveolaris is the most frequent source of toxemic iritis, and the reasons would seem to be, first, the great prevalence of pyorrhea, and, secondly, the fact that the infection in these cases is direct into the circulation, whereas in many other forms of alimentary toxemia the toxins undergo the ordeal of the hepatic furnace.

4. The Treatment of Fibromyomata of the Uterus.—By A. Donald. (See MEDICAL RECORD, August 22, 1914, page 353.)

5. Treatment of Contracted Pelvis in Pregnancy and Labor.—By H. Jellett. (See MEDICAL RECORD, August 22, 1914, page 353.)

7. Veratrine Treatment of Eclampsia.—By F. W. N. Haultain. (See MEDICAL RECORD, August 22, 1914, page 354.)

8. Rapid Relief in Acute Lumbago by Manipulation and Active Movement.—W. Haig believes that the suddenness of onset in acute lumbago is, in the first instance at least, a mechanical one analogous to "crick" in the knee, which may be so severe that but for the necessity of moving on and thereby setting in motion again the muscles which have suddenly come into a state of contraction it would be quite as crippling as an attack of acute lumbago. In view of the undoubted benefit in other conditions from the manipulations of the osteopath it occurred to the author to wonder whether physicians have not hitherto neglected the consideration of the spinal column as a series of individual movable joints. The author describes his method of treatment, which consists of deep thumbing of the lumbar muscles, in process of which a painful area is usually found in either the middle line or to one or other side; fixing the part of the vertebral column below this painful region by firm pressure of the thumb on each side of the spine; and making the patient perform movements of flexion, acute dorsiflexion, lateral flexion, and rotation. The result is the cure of the attack of lumbago, inasmuch as the patient is able to at once return to his work, and in no cases has the author had to repeat the process.

9. The Babinski Sign in Transient Functional Diseases.—F. C. Eve points out that dissections of those dying with organic nervous diseases show that Babinski's sign is due to a lesion in the pyramidal tract. Babinski's sign also occurs in certain diseases, such as uremic hemiplegia, which are too transient to be organic, so that in these diseases the hemiplegia must be due to a transient functional paralysis of the pyramidal tract. Yet in functional hemiplegia due to hysteria Babinski's sign is never present. The author concludes, therefore, that hemiplegia in hysteria is due to loss of function not in the pyramidal tract but in the neurons at some higher level in the brain. And he believes that this reasoning as to hysterical hemiplegia can be extended to other hysterical paralyses.

Berliner klinische Wochenschrift.

August 31, 1914

Diagnosis of Affections of the Pulmonary Apices.—Ehrmann states that differences in the percussion note of the two apices may mean nothing serious, and may be accounted for on anatomical dissimilarities in the two sides; while in other cases pathological alterations may be present but nothing tuberculous. Diminished resonance may be caused by pleural adhesions. It is true also in cadaveric percussion that dullness over the apices may be due to these same adhesions. It is known that in unilateral apical affections there may be anisocoria, or inequality of the pupillary width. The author has made a research into these cases after first giving atropine, 5 to 15 drops of 0.1 per cent. solution by the mouth. The pupils, measured each quarter hour, showed more inequality in apical affections—uni or bilateral—than in normal subjects. These differences could be brought out by adding one drop of 3 per cent. cocaine solution and one drop of 1 per 1,000 adrenalin. The atropin is given to paralyze the motor oculi. The reason why apical disease can increase the irritability of the dilator pupillæ muscle is not apparent.

A New Symptom of Brachial Neuralgia.—Meyer found that in three cases out of seven of idiopathic brachial neuralgia a symptom occurred which he terms "arm (or shoulder) pain with the head held in

the shaving position." The latter is a throwing backward and sidewise of the head toward the sound side. The pain is felt on throwing the head backward, but is intensified when the lateral movement is superadded. The author has never seen any description of such a symptom in literature. The first patient had to shave or be shaved while standing. A second patient grew a full beard rather than shave. When another patient with brachial neuralgia appeared the author was moved to a Sherlock Holmes coup. He bent his head strongly backward, and sidewise a little to the right. The patient at once complained of pain in his left arm with paresthesiæ. From simple pains in the arm, which are common enough, brachial neuralgia is easily distinguished by the induced symptom.

Cancer of the Dorsum Manus in an Old Scar.—Coenen first cites the case of the distinguished German surgeon von Bergmann who developed dysentery in the Russo-Turkish war of 1876 as a result of which he died in 1907. The process had left an ulcer in the colon and in the course of many years an annular scar had formed and caused an obstruction. Somewhat similar was a case of cancer of the back of the hand in the scar of a wound received in 1866, patient now (1913) being seventy-four years old. The scar had thus been intact forty-seven years. The cancer began as a verrucous growth replaced soon by an ulcer which discharged pus and spread until it had destroyed the entire back of the hand down to the bones. It had become frankly cancerous. The arm was amputated and the axilla cleaned out. The microscope showed a squamous epithelioma. The location is by no means rare in very aged men, and there may be a history of inception as a warty growth.

Münchener medizinische Wochenschrift.

August 18, 1914.

Action of Salvarsan on the Fetus.—Meyer has treated a large number of syphilitic pregnant women with special reference to the action of the drug on the placenta and fetus. His results are summed up as follows: the arsenic content of the placenta corresponded with that of the maternal blood circulating in the same. An intact placenta is not permeable to arsenic. A spyhilitic placenta may be traversed by arsenic but the frequency with which this occurs is unknown. Success in the treatment of a syphilitic fetus with salvarsan depends upon successful treatment of the maternal syphilis and is probably prophylactic rather than remedial. The drug is well tolerated by pregnant women. Intravenous injection does not provoke abortion or hemorrhage or fetal death. In a series of thirty-seven syphilitic pregnant women treated sufficiently with salvarsan and mercury combined, living children were born in 97.4 per cent. In a series of forty-three women so treated, 86 per cent. of children were alive on the tenth day and 15.8 per cent. of children gave a positive Wassermann reaction at birth.

Severe, Nondiphtheritic Stenosis of the Larynx in Children.—Köck reports two cases of this condition in detail. Clinically it is, of course, a form of croup. To which form does it belong? It could be one of four separate types of acute stenosing laryngitis. (1) Diphtheritic croup excluded from the outset. (2) Pseudocroup. (3) Atypical pseudocroup. (4) Phlegmonous laryngitis. The typical kind of false croup may also be excluded readily. It is the ordinary, familiar croup of childhood which attacks young children. The atypical form of croup usually attacks children of the school age, is at first an ordinary rhinolaryngitis in which stenosis develops slowly and steadily until severe air hunger demands intervention. The temperature, moderate at first, tends to become high. As a rule the condition rights itself spontaneously from the fourth to the sixth day. Both the author's cases were in nurslings, yet the parallelism with the pseudocroup in older children was unmistakable. One child, who did not make a clean recovery from the laryngitis developed a relapse and succumbed to pneumonia. The second attack of laryngitis was clearly phlegmonous, and the combined condition represented a pyogenic infection. Both intubation and tracheotomy had been resorted to. The case shows that pyogenic infection of the larynx causes greater injury than the Loeffler bacillus. Intubation therefore appears to be contraindicated.

Relapsing Umbilical Colic in Children.—Paula Tobias discusses the disputed significance of this symptom, and the necessity of excluding various familiar conditions in diagnosis, such as appendicitis and gastric or duodenal ulcer. The condition may have a purely angiospastic origin, representing a vascular crisis, and be associated with a vasolabile, neurasthenic or hysterical disposition. Such symptoms, according to some clinicians, forebode the appearance of ulcer of the stomach or duodenum. The treatment which seems to benefit these cases, in the absence of definite causal indications, includes rest in bed, a spare diet, belladonna, Carlsbad water, valerian, and any mild measures of suggestive character, such as strips of adhesive plaster applied to the abdomen. Two cases mentioned by the author were in children ten and thirteen years of age.

Münchener medizinische Wochenschrift.

August 25, 1914.

Diagnosis of the Form of Pulmonary Tuberculosis.—Romberg endeavors to individualize the various types of chronic tuberculosis of the lungs. Most readily isolated is the cirrhotic process. Even a duration of consumption beyond the two-year limit suggests it. The physical and rational signs correspond to the contraction of the lung away from the various portions of the thorax, the heart being drawn over to the affected side. Naturally the involvement of the lung must be extensive to produce the entire clinical picture. It is not difficult to isolate another form of tuberculosis, namely the progressive caseating, cavitary, or proliferative in which we see clinically frequent hemoptyses and profuse coin-like sputum. Infiltration is suggested by bronchial breathing, moist rales of metallic character, and increased vocal fremitus, while cavities are recognized by the characteristic physical signs. It is very common, however, to see these two forms of phthisis side by side in the same subject. In that case positive information as to the presence of each disease is not difficult to obtain. There is a so-called benign proliferative form which is not so readily isolated, because it bears considerable resemblance to the progressive caseating form, which for the most part runs a florid course. A differential diagnosis based on physical signs should hardly be practicable, and this is also true for the clinical history and rational signs as well as the bacillary finds. Under these circumstances the *x*-ray may be of value, because the benign proliferative form gives vague shadows. The consolidation is made up of proliferative tissue and atelectases, and in neither case do shadows result. Only when anthracotic indurations appear do sharp shadows form. The progressive caseating form, on the other hand, which is really a bronchopneumonia gives good shadows at an early period of the disease and these may be seen to increase in size.

Sleep Disorders.—Happich, before discussing the disorders of sleep, seeks a working hypothesis for the nature of sleep. In the most active as well as most passive phase of the brain we alike find hyperemia, which, however, should have a different mechanism in either case. In sleep the vascular dilatation is due to absence of tonus, while in mental activity it proceeds from excitation of the vasomotor center. Activity of the brain during sleep is concerned with metabolism. The brain cells unload their waste which is borne away by the dilated bloodvessels which also supply new building material. Activity of the brain during wakefulness results in, or is associated with, quickened mental processes, increased functioning. We do not yet know to what intent brain cell metabolism can occur during waking hours. The author seeks to prove that very much poor sleep is due to improper sleep positions, since these may interfere with the circulation. As a rule whatever causes active dilatation of the bloodvessels, such as coffee and hot baths, produces wakefulness. So whatever arouses attention has the same result—lights, noises. Drugs to produce sleep naturally should act on the bloodvessels. Narcotics are necessary only in insomnia from arteriosclerosis.

Acute Nephritis a Frigore.—Gehrmann's article on this subject appears in the Military Supplement, although the case reported occurred in a civilian. The idea is doubtless to call attention to the fact that exposure of soldiers in the trenches, etc., may determine a certain amount of renal morbidity. A man of twenty-eight while swimming became exhausted and his comrades were obliged to rescue him. His exposure in the water was from five to seven minutes only, but he was brought ashore in a state of collapse, with air passages obstructed by water and mucus. A half-hour's work was required for reanimation. In addition to routine measures he received oxygen and camphor hypodermics. Soon afterward he voided urine spontaneously which was brownish red like meat infusion, the sediment consisting chiefly of red blood cells. The patient died on the following day of secondary heart failure. Autopsy showed absence of any traumatism which could have caused hematuria. The kidneys, normal to the naked eye, were found to be the seat of an acute hemorrhagic nephritis. The patient had never had any serious illness at any time. This case had almost the force of an experiment, in that a single cause acting in a healthy subject brought about a definite result. But while the cutaneous exposure alone can cause acute nephritis in animal experiment, the internal saturation with cool water must also be reckoned as a factor.

Deutsche medizinische Wochenschrift.

Treatment of Tetanus with Subcutaneous Injections of Magnesium Sulphate.—Falk's contribution is made with especial reference to the possible use of this resource in the present war. Thus far it seems to have been tested subcutaneously in Germany in but four cases (three of tetanus neonatorum) all of which ended in recovery. The intralumbal method has received more attention. According to Stadler success was attained in two-thirds of the cases thus treated. Five especially severe cases treated thus in the Turco-Bulgarian war showed two recoveries. The treatment of tetanus neonatorum has shown the value of the subcutaneous injection of magnesium. Convulsions are overcome, feeding becomes possible, pain ceases, and patients sleep. But the drug appeared to threaten fatal arrest of respiration. In two cases life seemed to be saved by using intramuscular injections of calcium chlorate, as advised by Meltzer. In the third case the magnesium treatment was associated with chloral hydrate clysters and recovery was smooth. A study of the literature shows that respiratory phenomena by no means necessarily develop. Magnesium should never be given by intravenous injection, as it might prove fatal, even in small dosage. In Mielke's (German) case 3 grams daily were injected subcutaneously, his patient being a child of five years. In America adults required from 8 to 20 grams daily, the number of injections being three per day. Concentrations of from 10 to 40 per cent. have been injected. The subcutaneous injection seems to promise much for tetanus on the battlefield.

Protective Typhoid and Cholera Injections.—Fornet writes enthusiastically of the new Leishman vaccine. In 10,000 vaccinated the typhoid morbidity was but 0.5 per cent., while in 9,000 unvaccinated it was 3 per cent. Mortality was tenfold greater in the nonvaccinated, while morbidity was sixfold greater. These British results have been nearly equaled by the Americans. In Germany there is some prejudice against immunizing attempts because the original campaign in South Africa, while technically successful, reduced the mortality only from 12 to 5½ per cent., protection was very brief, and last but not least, there was a marked reaction, local and general. The subsequent efforts of Leishman and Russell led to the use of bacilli subjected to certain temperatures (one hour at 53° C.) instead of boiling the cultures. The lowest possible temperature, in fact, was used to kill. In regard to living cultures, they cannot be considered in connection with wholesale immunization. Fornet, in addition to profiting by the work of the English and Americans has perfected an albumin-poor vaccine with a view of reducing the chances of a reaction to a minimum. It has not yet been tested on a large scale. There appears to be no valid objection to the use of cultures prepared by Leishman's method. In regard to the present status of cholera immunization protection is conferred in 99 per cent. However, this figure does not dispose of the question. We have to ask who should be immunized, when should this be done, and what should be injected. There is great room here for differences in opinion based on individual experience.

Congenital Fissure of the Bladder.—Schliep states that there are three degrees of this malformation, to wit: inferior fissure, superior fissure, and ectopia. The surgeon may either do a plastic operation, suture the bladder wall or extirpate the bladder and divert the ureters elsewhere. While good may be accomplished in the individual case, many patients receive no benefit at all. The method of operative closure gives little hope, as with the necessarily small bladder there is a marked tendency to stone formation and incontinence. The author relates a case of superior fissure of the bladder, a rare malformation, operated on in Professor Bier's clinic. It was in a boy aged eight months. At the root of the penis, above, there was a cleft in the symphysis, through which urine escaped. The funnel like opening was formed of bladder mucosa. The penis contains a urethra and a catheter may be passed through the latter into the bladder. The sphincter is divided by the fissure. Bilateral inguinal hernia coexists. The mucosa which formed the funnel like opening was circumcised, the bladder mobilized, and invaginated by suture. A fistula was left which required operative closure. The patient was able to urinate through his penis. Over a year later he was in excellent condition. The bladder was fully continent, capacity nearly 50 c.c. Cystoscopic picture normal.

Insurance Medicine.

THE HEART IN LIFE INSURANCE.*

By J. S. LANKFORD, M.D.,

SAN ANTONIO, TEXAS.

THE mortality from heart disease in life insurance has increased very rapidly during the last twenty years, and the ratio of increase is greater each year. This fact and the vast knowledge on the subject which has come the last few years from the graphic tracings of various instruments makes it well for us to renew our study and discussion of the subject.

In life insurance the heart is a question of diagnosis and prognosis, and may be divided into five groups for consideration.

First—Gross lesions, uninsurable.

(*a*) Aortic regurgitation. First in importance because common and fatal, and easiest of all to diagnose. Ninety per cent. of the cases are due to syphilis, and it is the general effects of the disease that kills rather than the aortic disease. Again, late in the course of arteriosclerosis the process may involve the aortic region, and in a similar way myocarditis from whatever cause may damage the valves. The cardinal points in diagnosis are, enlargement, jumping arteries, and a wide range of pulse pressure. The pulse pressure may be from one hundred to one hundred and fifty mm. and is pathognomonic.

There is usually a collapsing pulse, and a diastolic murmur heard best at the apex. The applicant is likely to be pale on account of the unsustained circulation, and short of breath. It is possible to diagnose this disease by the blood pressure alone.

(*b*) Mitral stenosis. Characterized by a thrill felt most distinctly in the second right interspace, enlargement, a peculiar systolic or presystolic murmur rumbling throughout the systole and ending with a snap, and accentuation and duplication of the second pulmonic sound. Obstruction will certainly lead on to serious hypertrophy, disturbance of the function of the sino-auricular node and the bundle, with auricular fibrillation and other serious heart and also systemic results. It is the most fatal of all organic diseases of the heart uncomplicated at the beginning.

(*c*) Mitral regurgitation. The three chief points in diagnosis are hypertrophy, a systolic murmur at the apex, and accentuated second pulmonic sound. Death rarely occurs from this disease when uncomplicated, but the accompanying conditions as arteriosclerosis and nephritis, are very important. About 85 per cent. of all heart cases that we meet with in life insurance work will be one of these three forms of disease in the earlier stages mainly.

The danger in these cases is not so much from the obstruction, or the leaking, as from the complication of myocarditis. When the difficulty leads on to great enlargement, it is easy to see that the new tissue cannot be perfect and that there must be many points in the muscle where connective tissue or inflammatory products or scars compress muscle fiber, nerve or blood vessel to the serious interference with function; the heart can neither nourish itself well and preserve its rhythm, nor do the necessary work for the rest of the body.

There are many symptoms common to failing compensation in valvular lesions and myocarditis. In advanced cases there may be general arteriosclerosis, pulsating jugulars, enlarged liver, dropsy; in nearly all cases there is nephritis; in practically every case the blood pressure is high; inability to stop breathing, unconscious rapid breathing, and shortness of breath on exercise are very common symptoms. There may be acidosis, cyanosed lips and nails, heart block, auricular fibrillation, or the alternating pulse. Of course a case with these evidences of advanced disease would scarcely come up as an insurance applicant except in collusion of the agent and examiner for fraud, and even then the inspection report would more than likely protect the company. But very grave heart disease may be deeply hidden and obscure, and might escape us unless we are careful in every examination.

The first thing that usually attracts attention in insurance work is an irregular, intermittent, or rapid pulse.

In blood pressure and exercise we have an unfailing guide to the true condition. Whatever the abnormality the great question is the integrity of the heart muscle, the reserve force of the heart, for upon this chiefly depends the prognosis. The pulse should be counted, the heart examined, and the blood pressure taken, and then with the cuff attached to the arm the applicant should be exercised to the equivalent of climbing two flights of stairs and then re-examined quickly. Exercise when not too severe will regulate the pulse if the condition is simple. If serious disease is present the irregularity will be greatly increased. If the heart muscle is in prime condition the systolic pressure will jump 15 to 40 mm. and, tested every two minutes, will be found to resume its original place in 6 or 8 minutes. If the condition is bad, in a powerful effort of the heart to respond, the rise may be even greater, but the return will be exceedingly slow, sometimes requiring 20 or 30 minutes. If the state of the muscle is extremely bad and the reserve force exhausted, the systolic pressure may fall instead of rising and the diastolic remain stationary, or rise a little, creating a very small pulse pressure. It will be a long time before graphic instrument tracings are required in life insurance, if ever, but we have in exercise and blood pressure a thoroughly reliable test, and it is the duty of the examiner to be safe in his recommendation of every applicant.

Nothing so quickly and certainly reveals weakness or disease of the heart, or that splendid reserve power that means long life, as the blood pressure instrument. There is no question but the polygraph, the electrocardiograph and other such instruments are going to prove of immense value in diagnosis and prognosis, but of course they cannot come into general use in life insurance work so far as the examiner is concerned.

The rarer and minor forms of trouble, and obscure cases will yield the truth to blood pressure and exercise combined, and need not be discussed further.

Second—Cardiorenal group.

This is a large and important class, and it is well to study it separately because it is in large part due to our changed methods of living. Some months ago a letter was addressed to about six hundred health officers, medical directors, and leading medical men in the United States, the Latin American Republics, England, France, Germany, and Japan, inquiring whether there had been an increase in diseases of this class in the last twenty years, and if so, the

*Read before the medical section of the American Life Convention at Dallas, Texas, October 7, 1914.

cause. Nearly five hundred very interesting replies were received. Discussion of this important subject cannot be taken up in the limits of this paper, but one essential fact may be mentioned. It is the consensus of opinion that there has been a great increase and that it is due chiefly to nerve strain. A striking fact is that the two nations showing by far the greatest increase are rice eating Japan and meat eating America, the two nations living under the greatest nerve strain and worry.

It would seem that we have, first, nerve strain or worry, more or less continuous, then impaired digestion and autointoxication in which potassium indoxyl sulphate and its allies play a considerable part, then high blood pressure, a poisoned heart, and overworked kidneys, all leading on ultimately to arteriosclerosis, chronic myocarditis, and nephritis. It is this group chiefly that threatens life insurance companies because there seems to be no promise of relief from the conditions causing it.

Fortunately we have here ample protection in blood pressure and a careful study of the urine. Experience has led me to attach much importance to indican in excess, with numerous cylindroids, scattering hyaline casts, and the least elevation of blood pressure. This is frequently the first indication of serious trouble.

Third—Poisoned Heart.

This is a group where organic disease has not developed, and yet the heart is not up to a good standard. This heart is responsible for many a death that is put down in life insurance mortality records as pneumonia, typhoid fever, and scores of other names. It is a heart that may become organically diseased, and that certainly is not strong and does not stand acute disease well.

There are many causes of this form of trouble: Autointoxication from constipation, dilated stomach, collapsed colon, or other cause; kidney poisons; infection, including tuberculosis, and many other conditions. The pulse is lacking in volume, is too rapid, and responds excessively and too readily to exercise; the heart tires easily, and the blood pressure is low. By the auscultation method the sound is muffled, feeble, and lacking in tone. There is muscular weakness, the functions are poorly performed, and it is highly probable that there is some disturbance of the function of the ductless glands that usually combine to fight poisons of every kind. The low blood pressure is very significant.

Fourth—Organic Lesions, Insurable.

There is a small group of this kind entitled to standard insurance if we can but select them. Mitral regurgitation with limited hypertrophy perfectly compensated and uncomplicated, in suitable occupation; roughened valves following inflammation, where there is a murmur, but no other evidence of disease or other symptoms pointing to trouble that has existed and recovered leaving the tracks behind. Such applicants, however, should be thoroughly tested, for late in life they may show up serious disease with the vascular changes of age.

Fifth—Simpler conditions.

It is a well known fact that there are heart murmurs unaccompanied by organic disease. This must be determined by the exclusion of all disease by the proper tests rigidly applied.

Again there is a harmless arrhythmia, very common in the young, due to disturbed vagus action, and noticeable chiefly on deep breathing. The young applicant is likely to be apprehensive on examination, and the breathing may become a conscious process, not only changing from shallow to deep, but irregular, and the pulse may become correspondingly erratic. These sinus arrhythmias are of no consequence of course and should not be put down against the applicant. It is an easy matter to find whether there is some other cause for the irregularity. A little exercise, or putting his mind at ease, will usually regulate the pulse. Unimportant irregularity may be caused also by excitement, smoking, or trivial disturbance of the stomach.

In this group of insurable applicants belong those who have what is called "extra systoles," or premature contractions. For fifty years these cases have been unfairly treated by insurance companies. Many have been declined in young manhood and made miserable for a long life under the impression that they had some grave form of heart disease, because of intermittence or irregularity. The sino-auricular node located in the auricle near the entrance of the superior vena cava and its transmitting line of muscle cells and nerves communicating with the other parts of the heart, the bundle, is an exceedingly delicate structure, and easily disordered. Again, the heart may become "sensitized" at various points from nutritional cause, especially in the ventricle, and the ventricle not waiting for a "wire" from the pace making node may act independently and prematurely, causing an extra systole with its so-salled "compensatory pause." This may happen two to ten times a minute for hours then disappear for days or months.

Thus a heart may not be well balanced and yet be perfectly sound. This is especially liable to occur on account of the changes incident to age after 40.

It has been clearly proven by Mackenzie and Lewis, by means of cardiograms and polygraph tracings, that extra systoles may exist without important disease. Most of us can't afford the money and time that an electrocardiograph or a polygraph would cost, but in exercise and blood pressure tests we have a means of excluding the organic diseases in which extra systoles may occur.

The thing for us all to do, Medical Examiners and Medical Directors, is to study the important subject of the heart together and thoroughly post ourselves on the recent great advancement in knowledge. Then on examination to strip the applicant to the waist, and by inquiry, inspection, palpation, percussion, exercise, and blood pressure tests to protect the company against hazardous risks, and at the same time be just to the applicant.

When thoroughly and repeatedly tested out many of these "extra systolics" will be found entitled to standard insurance, and others to some form of policy, and it is unfair to the applicant and the company to bar them.

Blood Pressure.—Jackson says that blood pressure examinations before and after exercise, together with observation of the pulse rate and the general signs of respiratory embarrassment and cyanosis, are a valuable means of estimating cardiac efficiency, and applied to those past middle age, or presenting cardiac irregularities or murmurs, or in whom there is any reason for suspecting degenerative processes, they furnish valuable and permanent information as to the condition of the heart muscle.

Society Reports.

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

Twenty-seventh Annual Meeting, Held at Buffalo, N. Y., September 15, 16 and 17, 1914.

THE PRESIDENT, DR. CHARLES N. SMITH, TOLEDO, OHIO, IN THE CHAIR.

The Necessity of Constantly Looking for Cancer of the Uterus.—Dr. J. HENRY CARSTENS of Detroit drew the following conclusions: 1. Every case in which curetting was done should be examined. If it was done for miscarriage, it should be examined to show the remnants of placental tissue, and also to determine whether there might not be the beginning of decidua malignum. 2. If curetting was done for hemorrhage, one should know if it was due to a condition of the mucous membrane or was constitutional. If it was done for an irritating discharge one should know the pathological changes in the mucous glands. The important thing was that we wanted to know. 3. In every case of curetting the tissue removed must be carefully examined microscopically. In every case of trachelorrhaphy the tissue removed should be examined in the same way for cancer. 4. The age of the patient would cut no figure, old or young. All tissues removed should be subjected to the same careful microscopic examination.

DR. JULIUS H. JACOBSON of Toledo said if we could impress the nurses in the training schools with the importance of the early recognition of cancer, we could do more good in informing women of its early signs than by any other plan we might adopt.

Dr. CHANNING W. BARRETT of Chicago said he would not be inclined from the point of view of the development of carcinoma in the liver, the pylorus, or cervix, to lay as little stress as the essayist did on the point of irritation as an etiological factor. We would probably find out some time that there was another cause, a parasitic cause, yet it could not be doubted that irritation did play an important rôle in the causation of cancer.

Dr. FRANK D. GRAY of Jersey City said according to the essayist, the portions of the body most subject to irritation were the least liable to the development of cancer. He would like to have him explain that point more fully in his closing remarks.

Dr. GORDON K. DICKINSON of Jersey City said Dr. Beaver and he stood alone in exploiting the value of diagnostic hysterotomy. Dr. Carstens spoke of the pathologist finding cancer cells and making a diagnosis. How many times had we trusted our pathologists who sent a report back "No cancer found," and afterwards we discovered carcinoma? We should make a diagnosis early and he did not see any reason why when clinical and pathological proof was wanting, we should not bring the fundus down into the vagina, split it, examine the interior of the uterus, and remove a piece, if necessary, instead of relying on the curettings.

Dr. CHARLES L. BONIFIELD of Cincinnati said that he did not think it was wise to keep on harping to the laity about the early symptoms of cancer, because they could not make the diagnosis, but what was necessary was to teach married women who had had children the necessity of going to a gynecologist occasionally to be examined, just as they went to a dentist to see if their teeth were sound or decayed. If it was worth while to pay money to save the teeth, it was certainly worth while to have some competent man to determine whether or not a woman was suffering from cancer.

Dr. CARSTENS in closing said irritation did not produce cancer. It never had and never would. If by coincidence there was a place that was irritated and cancer developed, there was some other place where cancer developed where irritation did not exist. People who wore glasses irritated the skin of their noses; their noses were pinched, yet he challenged anybody to show him a single case of cancer having started there from such irritation.

Renal Damage from Calculi.—Dr. HENRY D. FURNISS of New York City said, from an experience of about four cases, he had come to the following conclusions: (1) Lithiasis was essentially a chronic disease. Undoubtedly the calculus in each case was present much longer than the symptoms, yet the average duration of symptoms was four years—the minimum being one month and the longest eighteen years. The development was often insidious, and frequently complete destruction of a kidney occurred with very little discomfort or interference with the general health. In only two cases, running a septic temperature, was the general health much impaired. (2) Multiplicity of stones was found in fifteen cases, though in only two were both sides affected. In calculus anuria this bilateral involvement should always be considered. The consensus of opinion was that sympathetic anuria was rare, and that in nearly every case it would be found that the unsuspected kidney had either been congenitally absent or previously destroyed by disease. Reflex pain was another condition that was to be looked upon with suspicion,—a definite cause for pain was generally to be found, and he regarded this so-called reflex pain as very rare. (3) Stones, unless multiple or very large, situated in the calices, in the absence of infection, or the opening of a blood vessel, by attrition, caused little discomfort and little damage. The size and location in these quiescent cases should be determined by frequent radiographs, and when the stone remained favorably situated and did not enlarge, a waiting policy should be the one used. When very large, pressure atrophy of the renal parenchymia occurred. (4) When a stone entered the pelvis of the kidney, then obstruction was likely to occur, and with the consequent retention infection would sooner or later develop. . . . The rougher the stone and the greater the retention, the greater the liability of infection, so the more urgent need of operation. Calculi able to be passed through the ureter, entered it soon after they had dropped into the pelvis from one of the calices. So we seldom saw pelvic stones that were subsequently passed. Stones in the pelvis that obstructed had many features in common with ureteral calculi. (5) Ureteral calculi that were small, smooth, did not completely obstruct, moved downward constantly, and were passed in a relatively short time, did only temporary damage. Those that were fixed, or obstructed seriously the outflow of urine soon led to irreparable damage, especially if infection took place. Stones in the pelvis that ball-valved it, and ureteral calculi, as a rule caused much more suffering and greater renal damage, than stones located in the calices, especially when upon the retention, infection supervened. Ureteral calculi often became embedded in the ureteral wall, and after operation, stricture of the ureter was very apt to occur, and caused further damage to the kidney. (6) The effect of calculi upon the kidney was dependent mostly upon the obstruction that was produced, and was added to by infection, which was present in 68 per cent. of his cases. There were nine cases of pyelitis and pyelonephrosis, five of pyonephrosis, and five of infected hydronephrosis. In seventeen cases the function of the involved kidney as compared with its fellow was determined, and in only two was it normal, in four the loss of function was moderate, in three great, and in eight complete. This analysis showed that in practically 50 per cent. there was damage to the renal function, and that in 35 per cent. it was completely destroyed. Their numbers fell short of showing the real condition, for in fifteen cases, nearly 50 per cent. of the total, no determination of function was made. (7) Of the thirty-two cases, the calculi produced no injury in thirteen, in nine there was pyelitis and pyelonephritis, in five pyonephrosis, and in five infected hydronephritis, and he believed it was fair to assume that some of the nine pyelitis and pyelonephritic cases would have in the course of time advanced to the stage of pyonephrosis and infected hydronephrosis; and that of the thirteen undamaged cases, many would later have become more seriously involved. (8) In the pyonephrosis cases and the infected hydronephrosis with great loss of function, nephrectomy was advisable. (9) In the ureteral cases with great loss of function, it was debatable whether the removal of the stone, or the kidney was advisable. His own opinion was that better results were obtained by removing the kidney than the stone, and that the best results came from removing the kidney and ureter to a point below the stone. As infection was one of the greatest dangers, our examination should be conducted with this in mind. The method upon which he insisted was radiography, first and always. The estimation of the damage done the kidney was best determined by observation, through a cystoscope, of the elimination of indigo-carmine injected intravenously. Occasionally, but not often, it was necessary to insert an *x*-ray catheter to be certain that a given shadow was in the ureter,—or to pass a waxed tip catheter when radiography failed.

Dr. CHARLES L. BONIFIELD of Cincinnati said he remembered distinctly a case he operated on two years ago. The patient went to one of his colleagues two or three years previously, had the kidney explored and needled, but the conclusion was reached that there was no calculus. In the meantime *x*-ray showed a calculus and its position, so that it was easily removed. It was important to *x*-ray all these cases early.

Dr. MILES F. PORTER of Fort Wayne said he would like to ask Dr. Furniss what, if any observations he had made regarding the incidents of cancer in kidney stones?

Dr. FRANCIS REDER of St. Louis said hardly any surgeon to-day would invade the kidney without having a positive *x*-ray picture. In one case he cut down upon a kidney following an *x*-ray picture which located the stone in the lower pole. At the operation it was found that the stone was an inch and one-half in the ureter. In some way the kidney was displaced and the shadow showed through the kidney and gave the impression the stone was located in the lower pole of the kidney.

Dr. LEWIS F. SMEAD of Toledo said he would like to ask Dr. Furniss what experience he had had with calculous anuria where the stone was small enough to pass, and whether he had been forced to operate upon small calculi on account of calculous anuria.

Dr. HUGO O. PANTZER of Indianapolis said he would like to ask what stress we might place upon bladder irritability as a symptom in these cases. Also what objection the doctor had to doing nephrotomy.

Dr. E. GUSTAV ZINKE of Cincinnati said a man, fifty-four years of age, came to him complaining of no symptom in particular except that he did not pass as much urine as usual, and that occasionally he would have a dull pain in his back. Examination of the urine revealed a slight trace of pus. The *x*-ray showed a stone about the size of a rooster's head upon the right side, with a stone about the size of a cherry upon the left side, which gave him very little or no trouble. In operating upon the kidney with a large stone, the kidney was easily found, exposed, and incised its full length to remove the stone. There was apparently no evidence of destruction of the kidney tissue, and as the man had a stone upon the other side he concluded not to remove the kidney. He sewed it up and fixed it in the usual way. The man did well for a week, and then suddenly began to go down. He had no evidence of peritonitis, and died of exhaustion at the end of two weeks.

Dr. BONIFIELD asked whether the kidney was drained or not.

Dr. ZINKE replied that it was.

Dr. JOHN F. ERDMANN of New York City mentioned a case in which a radiograph showed a large stone on the right side and a large shadow on the left side. The patient had a high temperature with all the evidences of sepsis. He operated on the left side and removed a large hypernephroma. He did not operate on the kidney containing the stone. Notwithstanding the man's urine was badly infected he had recovered. The speaker hoped later, if the man turned up, to do a nephrostomy and remove the stone from the right kidney.

Dr. FURNISS, in closing, said he had not had many cases of anuria. Where there was anuria we could not determine the relative function of the kidneys, because neither one was excreting. If we had only one chance to do one operation, it was best to do it on the side where the symptoms were the least because the other kidney might have been destroyed.

Anastomosis of the Gall Bladder to the Stomach: Cholecystogastrostomy.—Dr. JULIUS H. JACOBSON of Toledo drew the following conclusions: (1) The operation of cystogastrostomy had the same indication as that for cholecystenterostomy. (2) The presence of bile in the stomach after cystogastrostomy did not interfere with digestion or cause the patient any inconvenience. (3) The operation was very easy to perform; therefore, it offered a palliation and prolongation of life to a class of patients which, as a rule, were considered inoperable. (4) On account of the small danger of ascending infection it should be the choice of methods when it became necessary to anastomose the gall-bladder to the alimentary tract.

Observations on Torsion of Ovarian Cysts.—Dr. K. I. SANES of Pittsburgh said recognizing the dangers of torsion we should adopt only one line of treatment, and that was ovariotomy. Pregnancy should not be considered a contraindication to the operation. In a case of torsion of ovarian cyst and a case with torsion of the right tube and ovary during the fourth month of pregnancy both went to full term and were delivered of living children about five months after the operation. The operation was simple and safe, and even the finding of peritonitis and ascites did not seem to affect the results. In cases of impaction of a twisted cyst in the pelvis, the vaginal route might be preferable. The good result of the vaginal ovariotomy in one of his cases showed that in favorable instances it could be safely used. There was no death in his ten cases. There were four deaths among the twenty-five cases collected from literature, one from acute nephritis, secondary to toxemia, one from yellow atrophy, secondary to toxemia, one from perforation of the sigmoid, caught in the twist, and one from sepsis.

Dr. CHANNING W. BARRETT of Chicago said the question as to how to deal with an ovarian cyst and yet save the ovary was an important one. In a series of cases collected the frequency of abortion following operation was almost in direct proportion to the trauma done beforehand. The further question that was brought out in this series was what to do with an ovarian cyst that was double, there being a rather common notion that if both ovaries were removed abortion would take place. Abortion did not occur in the series of double removal of the ovaries, but slightly in a single ovary, and that was easily accounted for by the extra manipulation of taking out the two ovarian tumors rather than one.

Dr. ALBERT GOLDSPOHN of Chicago said if we inspected the outer part of the cyst wall near its pedicle frequently we would see macroscopic evidences of Graffian follicles and he had repeatedly dissected out that outer layer, carefully ligated vessels, without compromising the main pedicle, and folded the flap up and stitched it, and menstruation had followed from that.

Dr. HUGO O. PANTZER of Indianapolis said he had had a singular experience, namely, fourteen cases of torsion of ovarian cysts in fourteen consecutive months, and then none in two years plus.

Delayed Union in Noninfected Epigastric Wounds.—Dr. MILES F. PORTER of Fort Wayne said the evidence upon which rests the opinion that delayed union was more likely to occur in wounds in or near the midline above the umbilicus than in similar wounds below the umbilicus was quite strong. Neither the suture material nor the method of suturing could be blamed in all cases. The causes were many. Of special importance was the general condition of the patient. By using non-absorbable suture material, and allowing the sutures to remain *in situ* for two weeks or more, one might avoid serious accidents from delayed union; but one could not in this way always secure prompt union. Incisions through the recti muscle united more promptly than incisions through the white line. The result of delayed or imperfect union were immediate and remote. The immediate result was protrusion or exposure of the viscera, and the remote result was hernia and rarely rupture of the scar. Lack of union was usually symptomless and was usually discovered when the wound was dressed. In some cases the moisture of the dressing led to an example which revealed the conditions. As a rule, the prognosis was good. The proper closure of wounds might not secure prompt union, but would prevent serious accidents from delayed union.

Dr. GEO. VAN ANBER BROWN of Detroit said he had had three cases similar to those described by Dr. Porter. The first occurred about ten years ago in a young woman for whom he had removed a large cystic ovary and did the so-called Gilliam operation. She did nicely and left the hospital in fifteen days. Two or three days after her return home he was called and found the wound had separated down to the peritoneum. There was no suppuration. It was filled with one blood clot. A culture was made and staphylococcus infection was found. She was taken to the hospital and the peritoneum closed with catgut and a layer of gauze placed between the peritoneum and the muscle for drainage, and then the muscle sheath closed with catgut, and she made an uneventful recovery.

Dr. LEWIS F. SMEAD of Toledo reported two cases of delayed union above the umbilicus. The first was a case of pyloric obstruction due to ulcer in which the Finney pyloroplasty was done. It was a right rectal incision. The wound was closed with fine silk in the peritoneum, and muscle and fascia with heavy silk, running silk in the fascia, the through-and-through muscle fascia stitches going back three-quarters of an inch and tied over a running stitch, the skin being

closed by subcutaneous silver wire. At the end of ten days the silver wire was removed and the wound was apparently clean. In the afternoon the wound opened completely from end to end. It was closed immediately, but the woman died on the seventeenth day from peritonitis.

Dr. Asa B. Davis of New York City said he had seen five or six cases of separation of the wound after cesarean section in the Lying-In Hospital. The wound was not infected apparently, but by closing it again with through-and-through silkworm gut sutures there were strong union and no complications. In one or two cases the wound had been infected and opened part of the way down and had been allowed to heal by granulation. In these cases hernia developed, while in the other cases it did not. It was a rare thing to see in connection with cesarean operations. He did not recall one in any of his own cases.

Dr. Albert Goldspohn of Chicago said it must be evident to almost all of us that when we tried to close epigastric incisions the structures seemed to give with much more tension. There seemed to be a greater shortage of material in the epigastrium than in incisions made below the umbilicus. Dr. Goldsphon then related a case in point.

Dr. Hugo O. Pantzer of Indianapolis said he operated on a patient in the relatively well period of pernicious anemia. In that case, within three days after operation there was not found a vestige of any absorbent suture material, and he used chromic gut of the heavy type through the fascia, so that he had to recognize in such cases systemic or blood conditions.

Dr. Frank D. Gray of Jersey City said the only instance of separation of the abdominal wound which he could remember in the course of five years or more was a laparotomy done for resection of the intestine following a bullet wound, making six or seven openings in the intestine, which he resected and united by the modified Maunsell method, and the man made an uninterrupted recovery. For a week there was no evidences of sepsis. At the end of the time he sat up, was put in a roller chair, and on his own responsibility went rolling around the wards. He went back to bed in partial syncope and vomited. The wound separated. It was closed again, and he made an uneventful recovery with perfect union.

Dr. William H. Humiston of Cleveland said he did not see why we should have more difficulty with incisions made in the epigastric region than in those made below the umbilicus. The question arose whether the technique might not be at fault in the majority of cases. It was better to go through the muscle to the right of the median line and be very careful not to strip the fascia from the muscle. If the incision was clean and the muscles were separated carefully, and the posterior fascia was divided carefully, he did not see why there should be separation of the wound. In the majority of cases where separation occurred the muscle sutures were drawn too tight.

Dr. Porter in closing said, he was in exactly the same fix as Dr. Humiston, and did not see why we should have this separation of the wound, but the fact was we did have this trouble, and he wanted to find out why we had it. There was no question but that there was greater danger of lack of union in a given wound above the umbilicus than below it.

Myomectomy with Extensive Resection of the Uterus in Fibroid Tumors.—Dr. X. O. Werder of Pittsburgh said a comparison of the mortality of hysterectomy and myomectomy would seem to be rather in favor of the latter according to the experience of the writer. Since 1898 inclusive, during which time accurate records had been kept, 707 cases of uterine fibroids had been operated upon with a total mortality of 3.25 per cent. This did not include over a hundred cases in which small fibroids were removed coincident with other operations, but only those in which this neoplasm constituted the principal indication for operation. In these 707 cases, hysterectomy was performed 536 times and myomectomy including the 13 cases of extensive resection of the uterus here reported, 171 times. The total mortality in the latter cases was 4 or 2.33 per cent., while hysterectomy was accompanied by a death rate of 3.45 per cent. or more than 1 per cent. in favor of myomectomy. The morbidity of myomectomy also compared even more favorably with that of hysterectomy, as the cases of myomectomy almost uniformly made a smooth, uncomplicated recovery, and almost without exception enjoyed perfect health after the operation; they were, in fact, among the most satisfactory cases in the writer's experience. In conclusion, he felt therefore, justified in making a plea for more conservative treatment of uterine fibroids in younger women than they now received at the hands of most general surgeons and gynecologists. Myomectomy and the more radical resection of the uterus could be profitably performed in many women whose uteri were now ruthlessly sacrificed, resulting in many cases in long years of discomfort, unhappiness, and often invalidism.

Dr. Gordon K. Dickinson of Jersey City said he would like to ask the essayist whether he had had any cases of embolism from myomectomy.

Dr. J. Henry Carstens of Detroit said if he had a young woman who had one or two fibroids, he performed myomectomy. If she had a number of small ones, he was inclined to remove the uterus. In some cases he had taken out one side of the uterus, about one-half, but had not tried systematically to save any uterine tissue by taking away half of it or one-quarter of three-quarters. It seemed to him it was a matter of very little consequence whether we took it all away or half of it. If the ovaries were intact and they were left, it did not make any difference whether we took out the whole uterus, or half of it, and whether these women menstruated afterwards or not was of no great moment, because he did not think menstruation was of benefit to them. The question of ovarian secretion was all important, and if we left the ovaries the woman would go on and never know whether the uterus was out or not, except that she did not menstruate every month.

Dr. Robert T. Morris of New York City said there was one important factor we were apt to forget, and that was the patient herself. We should ask her what she wanted. To a patient who had these small masses, he said, if he did a myomectomy removing a part of the uterus and leaving a part, she would probably have a further development of this neoplastic growth because the original conditions persisted. If she wanted him to leave a part with the possibility of having further neoplastic growth develop, with the idea of having a child, all right. If one woman said yes, he left it for her. If another woman said no, he took it all out for her. He left it to the patient to decide.

Dr. Hugo O. Pantzer of Indianapolis said the importance of Dr. Werder's contribution lay in the fact that he had materially lessened the mortality by not removing the entire uterus. To Dr. Pantzer that was a very strong and sound argument in favor of myomectomy as against a more radical operative procedure.

Dr. Julius H. Jacobson of Toledo said, in reference to the *x*-ray treatment of fibroids, last year, after the meeting at Providence, Dr. McClellan and he went abroad and were much impressed in the clinics they visited with the number of sloughing fibroids in patients operated upon after *x*-ray treatment had been applied. He came to the conclusion that these cases treated with the *x*-ray gave a larger mortality than cases operated upon when the fibroids were smooth, when myomectomy and hysteromyomectomy could be performed.

Dr. A. B. Miller of Syracuse said we saw very few large fibroids at the present time as compared with former years, and if the line of treatment advocated by Dr. Werder was carried out, he was sure the results would be satisfactory. In connection with fibroids in women of advanced age from the fact the menopause did not cease, many women would either not accept operation or, owing to associated conditions of heart disease, general debility, anemia, etc., it was impossible to subject them to operative interference without mortality. He had had six cases of fibroid tumors in women of advanced age that had been treated with *x*-ray with very good results.

Dr. Werder in closing said, in regard to deaths from embolism, he had had a number of embolic deaths, and they were included in the three and one-quarter per cent. mortality, but only one embolic death from myomectomy. Other embolic deaths had been from hysterectomy.

The Kinetic System and the Treatment of Peritonitis.—Dr. Geo. W. Crile of Cleveland said an analysis of the leading phenomena of peritonitis—pain and tenderness, distention, muscular rigidity, vomiting, intestinal paresis, as well as of the general symptoms of infection—accelerated pulse and respiration, raised blood pressure, fever and rapid loss of strength and weight—showed that they were adaptive phenomena evolved by the abdomen for the purpose of overcoming infection. The peritoneum, through natural selection, had acquired the power of overcoming infection by immobilizing the point infected by (a) inhibition of the intestines; (b)

distention of the intestines; (c) rigid persistent contraction of the abdominal muscles; (d) further fixation by the pouring out of a sticky, glue-like fluid. In peritonitis, as in physical exertion of any kind, the transformation of energy utilized for this purpose might be so rapid and extensive that exhaustion—death even—might follow. This exhaustion was further increased by the loss of water due to vomiting and to the diminished intake. As a result of this and of the increased blood supply to the intestines, there was a shrinkage in pulse volume, and the amount of urine was decreased coincidentally with the increased metabolism. Safety, therefore, might lie in the control of the kinetic system by which excessive energy transformation was retarded and the water equilibrium was maintained. Deep morphinization caused inhibition of the intestines, immobilized the body as a whole, prevented both pain and muscular rigidity, held metabolism at a standstill, and thus reduced the drain upon the body's stores of energy. Therefore if energy transformation was minimized by morphine given in large physiological doses and if the water equilibrium was maintained by the installation of water the point of infection was immobilized while the phagocytes overcame the infection, and at the same time the brain, suprarenals, and liver were protected and the energy of the patient was conserved.

End Results after Operation in 109 Cases of Displacement of the Uterus, Bladder, and Rectum.—Dr. H. A. Wade of Brooklyn drew the following conclusions: Morbidity and not mortality should be considered in all operations for the correction of displacement of the pelvic viscera. The morbidity would be less in replacements by the vaginal route than by the abdominal. The relative position of the body of the uterus to its cervix should be considered in the relief of symptoms, and not the position of the uterus in its relation to the other viscera of the pelvis, except in cases of marked procidentia. A movable uterus out of place would give rise to fewer symptoms than a well placed uterus not freely movable, and a movable uterus that had been suspended would give rise to no untoward symptoms during labor. Old tears of the perineum might be repaired three days after labor or after abortion with assurance of success.

Ruptured Gastric and Duodenal Ulcer.—Dr. Edgar A. Vander Veer of Albany said as to treatment, there was but one thing to do, and that was to operate as soon as the diagnosis was made. He preferred a good free incision in the right semilunaris, enabling one to readily inspect the entire right side of the abdomen. Experience had shown that the majority of perforations had occurred at the pyloric end of the stomach or the first portion of the duodenum, and this incision gave us an exposure of the field and plenty of room in which to work. The perforation having been located, it could be closed in one of several ways. A couple of continuous Lembert sutures seemed to be effective and quicker than any other method. If possible the sutures should be inserted parallel to the long axis of the stomach or duodenum so as to interfere as little as possible with the circumference of the gut when the scar contracted. As a rule, the condition of the patient would not permit the performance of a gastroenterostomy, as some advised. If this was necessary it could be done at a second operation, when the patient's physical condition was improved. A rubber or cigarette drain should be placed in the lower angle of the wound, leading down to the point of perforation. A secondary incision should be made in the right iliac fossa and drainage inserted in order to remove the fluid which seemed to collect there. While he did not wish to be considered as criticising the internist too much, still he felt that very frequently cases of chronic and gastric duodenal ulcers were treated by a gastroenterologist and claimed to be cured, whereas they needed the attention of a surgeon. If these cases could be reached by the surgeon sooner, the number of perforations would be far less.

Repair and Reconstruction of the Bile Ducts.—Dr. J. H. Jacobson of Toledo drew the following conclusions: (1) The possibility of accidental injury to the common and hepatic ducts must not be forgotten in every operation for the removal of the gall-bladder. (2) Such accidents arose owing to the atypical junction of the cystic with the hepatic and common ducts. (3) The larger bile ducts could be repaired either by simple suture or by end-to-end anastomosis. The anastomosis should allow for drainage for the hepatic ducts. (4) Portions of omentum, pieces of the gall-bladder and flaps from the stomach had been successfully employed to cover defects in the walls of the ducts. (5) When a sufficient portion of the hepatic duct remained it might be anastomosed into the stomach, duodenum, or small intestine after the method of Witzel. (6) A new common bile duct might be formed by transplanting a piece of small intestine for the purpose, and where possible this should be the method of choice. (7) Owing to the wonderful regenerative power of the bile ducts a complete new duct could be formed by the aid of a rubber tube connecting the remains of the hepatic duct with the stomach, duodenum or jejunum. (8) While the immediate results were good, the ultimate results were not known; therefore, the method should be used only in debilitated patients.

Pyloric Stenosis.—Dr. Charles L. Bonifield of Cincinnati reported a case of pyloric stenosis in an infant, operated on by the method of Dr. John W. Keefe. The simplicity of the operation and the fact that it could be done in a few minutes, and that it was technically much easier than a gastroenterostomy in an infant, and the further fact that it left the organs in normal relation should recommend it to surgeons. The author believed its general adoption would reduce the mortality rate, which was now about 50 per cent., very materially in this condition.

The Treatment of Urinary Calculi as Based on Their Chemical Composition.—Dr. Charles B. Schildecker of Pittsburgh said an attempt had been made in this paper to call attention to the importance of the chemical examination of urinary stones and also the treatment of same as based upon their chemical composition. While our knowledge of all chemical factors that played a part in the formation of urinary calculi was limited, still it was our duty to apply the knowledge we did possess at the present time. He had no doubt that the application of the principle mentioned in his paper would prove of service in the treatment of calculi, both as regards their new formation and also their further increase in size and number.

Report of a Year's Work with the Abderhalden Reactions.—Drs. A. J. Skeel and W. C. Stoner of Cleveland said of eleven cases eight were positive to placental and cancer albumin. Two were negative to both. One was not tested for cancer albumin. Among nine eclamptics and severe pre-eclamptic cases eight gave positive reactions of unusual intensity. One was negative. Syphilitics both before and after salvarsan showed the usual reactions. Of sixteen sexual perverts from the Cleveland State Hospital, all non-pregnant, eight were positive and eight negative. Of the positive non-pregnants, nine were cancer, three fibroids, one pseudocyesis, four inflammatory conditions, eight sexual perverts, two unexplained. Total, twenty-seven. The reaction in our small series of sexual pervert cases suggested further investigation along this line. Might it have to do with tissue system reactions? In future cancer cases they would endeavor to specify the location of the growth and the source of the cancer albumin. Conclusions: (1) The Abderhalden ferment test was delicate and required great care and considerable experience for successful work. (2) Because of the great variety of conditions which might give the reaction positive results it could not be taken as conclusive evidence of pregnancy. (3) The negative reaction if repeated and well controlled was quite reliable as an indication that the patient was not pregnant.

Abdominal Distention Following Operations upon the Pelvic Viscera.—Dr. Francis Reder of St. Louis said in former years he attributed this condition to the improper preoperative care of the patient and to a lack of surgical proficiency. Not only did abdominal distention follow pelvic work, but it might also manifest itself in any and all abdominal operations, even including operations on the kidneys, which were extraabdominal organs. The surprising feature of this abdominal distention was that it might manifest itself with the greatest discomfort in an operation of a lesser magnitude, whereas in an operation of greater magnitude, and where such distress might be expected, the postoperative period might be surprisingly free from this phenomenon. Could an uncomplicated abdominal distention following a laparotomy menace the life of a patient? When the factors at work were fully considered, this question must be answered in the affirmative. The most encouraging measures at our disposal were embodied in the stomach lavage and in the enema. The former should be used every four to six hours while the patient continued to vomit, whereas for the latter it might be said that our greater hopes rested there. In his hands the alum enema of Hardon, slowly introduced into the rectum every two hours, if neces-

sary, had proven so efficacious that he had given it the preference over all enemata. The alum was not irritating to the bowel, so that a large number could be administered provided the nurse exercised gentleness. His experience with pituitrin given in connection with the alum enema had been limited to eight cases. Its administration had favorably influenced the vomiting in five of the eight patients.

Two Cases of Cancer of the Uterus Apparently Cured by Postoperative Infection.—Dr. JOHN W. POUCHER of Poughkeepsie said in both these cases the laboratory reports showed the disease to be adenocarcinoma, and in neither of them could he claim to have removed all the diseased tissues, consequently the cure must be attributed to some other cause, namely, the suppuration and the formation of a toxin that destroyed the cancer cells. There were areas of broken-down tissue filled with masses of dead cancer cells. The operation opened up fresh fields for their absorption. Might we not have here a genuine auto-inoculation of dead or modified cancer germs? In the literature he found several instances of spontaneous cures of cancer and several pathologists with whom he had discussed this subject said they had found post-mortem evidences of such cures.

Operations at the Home; When and Under What Circumstances Are They Justifiable?—Dr. J. E. SADLIER of Poughkeepsie said in order to prove the relative merit of hospital *versus* home operations, one must have recourse to statistics as to mortality, and in this particular subject they were difficult to obtain. One must always consider that cases operated at home represent a severe type of the emergency class, and many of them suffer from sepsis or toxemia. Under such conditions, one could not expect to have as good mortality rate as in hospital cases where elective work and uninfected cases were the rule rather than the exception, and yet in his surgical work in the hospital covering a period of twelve years, in 1902 to 1914, and with an average of 60 per cent. abdominal work, there was a mortality of 3.4 per cent. The average mortality during the past three years was 2 per cent. No attempt was made to exclude any properly operative cases and all patients dying in the hospital regardless of when or what complication were included. After a careful and exhaustive study of his results when operation was done at the home, covering the same period of twelve years, he found that the mortality was 4.3 per cent. When we considered that the home operated cases represented the severest type, and that the performing of elective surgery at the home was discouraged, he thought the above statistics, covering several thousand hospital and home cases, about 20 per cent. being operated at home, spoke for a fair amount of safety for the home operation.

Pregnancy and Incipient and Inactive Tuberculosis.—Dr. WILLIAM GORDON DICE of Toledo said if there were pelvic conditions giving rise to real symptoms, such operation as might be necessary should be done, but the patient should be given to understand that the real cause of most of her ill health was in her chest, and not in the pelvis. Since future pregnancies were advised against, the natural question that arose was, should these patients be sterilized? In progressive tuberculosis, Bacon and Hoehne, as well as others, had advocated operations on the tube; Bumm and Martin had advocated hysterectomy; Bardeleben, excision of the placental site through the vagina and Gauss *x*-ray sterilization; but it must be the rare case of this type of tuberculosis that would submit to any of the more radical of these procedures, for the procedure itself might so lessen the vitality and resistance as to light up the latent process, even if the operative mortality were nil.

Treatment of Puerperal Thromhophlebitis.—Dr. JAMES F. BALDWIN of Columbus referred to the previous papers by Williams of Baltimore, who reported five personal cases with one death, and by Jellett of Dublin, who reported five cases with two deaths. The author reported four cases with one death. The object of the report was to describe the technique, which differed from that employed by previous surgeons, Williams having advised ligation of the arteries only, the veins being left wide open for drainage into gauze fluff which filled the pelvis and was brought out through the vagina, the sigmoid being sutered all around to the pelvis so as to completely isolate the peritoneal cavity. This gave the fullest drainage with the least trauma, and removed the original source of infection.

Ectopic Pregnancy and the General Practitioner.—Dr. BENJAMIN RUSH MCCLELLAN, of Xenia, reported four cases. Cases 1 and 4 were reported as overlooked extrauterine pregnancies which became infected, and thereby not only placed these lives in greater jeopardy, but added greatly to the chance of unnecessary invalidism. Contrary to the accepted rule, the abdomen was opened in each of these infected cases. This was done because of inability to secure satisfactory drainage per vaginam. Case 2 illustrated the importance of prompt intervention where hemorrhage persisted. Case 3 was a typical hematocele due to the pregnant tube rupturing unto the broad ligament, and which, recognized early, was easily removed, and thus stood quite in contrast to cases 1 and 4.

Bacteriological Findings in the Urine in Cases of Kidney Ptoses.—Dr. DAVID HADDEN of Oakland said the amount of trouble from ptosis depended more upon the interference with the flow of urine and the amount of stasis produced than upon the particular location of the organ. The stasis alone might result in symptoms of a uremic character, but from the kind of infection imposed would depend the degree of general pathological disturbance. The sensitiveness of the patient to defective physiology had a great influence upon the degree of stasis and the amount of infection necessary to give rise to symptoms essentially pathological. If the peristaltic action of the kidney pelvis and the ureter was perfect, the ptosis could be accepted as one not requiring correction, but we must realize that in every such individual the foundation for future trouble was present.

Operative Findings in Twelve Cases of Chronic Intestinal Stasis.—Dr. WILLIAM SEAMAN BAINBRIDGE of New York City said in addition to the usual symptoms as observed in a fairly typical case, Lane had called attention to a series of symptoms and diseases which he believed to be the outcome of chronic intestinal stasis, and which had been called the end results. He had enumerated a fairly comprehensive list of diseases which he believed to be traceable to chronic intestinal stasis, or to the lowered resistance which resulted there from, among which might be mentioned rheumatoid arthritis, tuberculosis, goiter, and cancer. It was to the last named disease that he wished to direct especial attention in this connection. He was not prepared to say, at the present time, how far chronic intestinal stasis affected the development of cancer. The whole problem of cancer was so involved that we could merely hypothecate concerning its etiology. The interrelationship of ulcers of the gastrointestinal tract and cancer of this region, of chronic irritation, as shown in one of his cases, and cancer, and of those conditions with chronic intestinal stasis, furnished food for thought. The last three cases of the series seemed to be significant in the light of some of the possible end results of stasis.

Plastic Operation for Correction of Cecocolon Stasis.—Dr. EMERY MARVEL of Atlantic City stated that delayed expulsion of fecal material was detrimental to health, and the retention of such matter became a bacterial and toxic menace. The deformities in and malposition of the intestinal tract predisposed to stasis. The cecocolon sac was the most common part involved. The condition was physical and invited physical correction. The author described a method of correcting the evil. With the method he conserved the structures, maintained function, and thereby occasioned a minimum risk and inconvenience to the afflicted.

Factors Determining Morbidity of Surgical Cases.—Dr. CHARLES W. MOOTS of Toledo said the mortality rate had long received much attention, while the morbidity had been neglected. The surgeon was a factor, together with his personality and general character upon the patient. The patient should be prepared not so much from a technical point of view as from the psychical. There should be the removal of all adverse stimuli. A correct diagnosis was of importance before operating. A long preparatory course of treatment should be abandoned. The author considered local and general anesthesia, position of the patient during operation, suture material, time consumed at the operation, and the method of handling the patient during the postoperative period.

Resection of Ovaries.—Dr. ALBERT GOLDSPOHN of Chicago said this procedure was almost wholly an incidental or auxiliary one, to be done when abdominal section was needed for other reasons, chiefly for displacements of the uterus, freeing of adhesions, and re-

moval of neoplasms from the uterus or its annexæ. The objections to it were theoretically (a) that all the hydropic Graffian follicles and follicle cysts of any size did or might contain ova, and, therefore, being psysiological structures, should be left alone. This claim was soon proven to be unwarranted and untrue by numerous investigators of the histology. (b) That these follicle cysts and cystic corpora lutea caused no symptoms, had been abundantly disproven by clinical experience by unbiased observers. Pain continued from such resected ovaries, too frequently, and secondary operations were too often needed for their removal. This had likewise been demonstrated to be untrue by several operators, aside from his own experience. According to newer studies, these follicle cysts and persistent corpora lutea sometimes gave rise to hemorrhages, even of a fatal nature; likewise, they might furnish an atrium for infection by bacteria or neoplasms. In his paper he pointed out the kinds of ovaries that were best suited for resection and the feasibility of saving ovarian tissue from the wall of larger ovarian cysts. Elevation or suspension of ovaries to relieve venous engorgement was of equal importance and must not be omitted after resection. It was important, Dr. Goldspohn said, to adhere to a strictly aseptic technique and the use of fine and readily absorbable suture material only.

The Use of Scopolamine-Morphine Narcosis in Labor.—Drs. A. J. RONGY and S. S. ARLUCK of New York drew the following conclusions: (1) Standard solutions were absolutely essential for the success of this treatment. (2) No routine method of treatment should be adopted. Each patient should be individualized. (3) Facilities should be such that the patient was not unduly disturbed. (4) A nurse or physician must be in constant attendance. (5) This form of treatment was best carried out in hospitals, although there was no reason why it could not be accomplished in well regulated private houses. (6) It did not affect the first stage of labor, but the second stage was somewhat prolonged. (7) Pain was markedly diminished in all cases, while amnesia was present in the greatest number of patients. (8) This treatment did not in any way interfere with any other therapeutic measures which might be deemed necessary for the termination of labor. (9) Fetal heart sounds must be carefully watched. Sudden slowing called for immediate delivery when possible or the discontinuance of the treatment. (10) Oligopnea was present in 15.2 per cent. of cases. However, normal respiration was very soon established and no ill effects were observed. (11) No change in the course of the puerperium was observed and convalescence progressed very smoothly in the entire series.

Scopolamine-Morphine Seminarcosis in Labor.—Drs. JAMES A. HARRAR and ROSS MCPHERSON of New York City contributed a joint paper on this subject in which they said that in the use of this method the profession had a valuable means of abolishing the woman's recollection of the ordeal of labor, in from 60 to 70 per cent. of cases, and they believed that in conscientious and painstaking hands, by a strict adherence to the proper technique, the possible dangers might be foreseen and avoided.

The following papers were also read: "Abdominal Drainage," by Dr. John W. Keefe, Providence, Rhode Island; "Some Thoughts and Views on the More Common Gynecologic Conditions Necessitating Operation," by William H. Humiston, Cleveland, Ohio; "Some Observations on the Technique of Intestinal Anastomosis, With Special Reference to a Modification of Maunsell's Method," by Dr. Frank D. Gray, Jersey City, New Jersey; "Mineral Springs of Saratoga," by Dr. Douglas C. Moriarta, Saratoga Springs, New York; "Biliary Surgery," by Dr. John F. Erdmann, New York; "Transverse Involution of the Colon; A Technical Step in the Short Circuiting Operation," by Dr. Robert T. Morris, New York; "The Statistics of Labor in Elderly Primiparæ," by Dr. James Roy Freeland, Pittsburgh; "The Treatment of Abortion Upon the Basis of Its Pathology," by Dr. Channing W. Barrett, Chicago.

Officers.—The following officers were elected for the ensuing year: *President*, Dr. Charles L. Bonifield, Cincinnati, Ohio; *First Vice-President*, Dr. Asa B. Davis, New York City; *Second Vice-President*, Dr. K. I. Sanes, Pittsburgh; *Secretary*, Dr. E. Gustav Zinke, Cincinnati, Ohio, reelected; *Treasurer*, Dr. Herman E. Hayd, Buffalo, N. Y., reelected.

Pittsburgh was selected as the next place of meeting in September, 1915.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

ILLINOIS STATE BOARD OF HEALTH.

(*Continued from page* 614.)

January, 1914.

NEUROLOGY.

1. Define and give etiology of acute ascending paralysis.
2. By which nerves is the heart controlled?
3. Where are the speech areas situated?

PHYSICAL DIAGNOSIS

1. Describe herpes zoster.
2. Give differential diagnosis between acute bronchitis and lobar pneumonia.
3. How would you determine high blood-pressure? What is its significance?
4. Give physical signs of aortic regurgitation.
5. Give distinctions between organic and functional heart murmurs.

OPHTHALMOLOGY AND OTOLOGY.

1. Differentiate between trachoma and conjunctivitis.
2. Describe, in detail, how you would treat a chemical burn of the eyeball.
3. Give symptoms, etiology, and probable serious results of mastoiditis.

PEDIATRICS.

1. Give differential diagnosis between measles and scarlet fever.
2. Give cause and treatment of "summer diarrhea."

PRACTICE.

1. Give the diagnosis and treatment of lobar pneumonia.
2. Outline the modern treatment of syphilis in the acute stage.
3. Give the differential diagnosis of cirrhosis of the liver.
4. Give the treatment of la grippe and its complications.
5. Give the treatment of tapeworm.
6. Give the treatment of the conditions in which headache is a prominent symptom.
7. Give the treatment of constipation.
8. Give the diagnosis, cause and treatment and prognosis in locomotor ataxia.
9. Differentiate endocarditis from pericarditis and give the cause and treatment of the former.
10. Give the cause and treatment of chronic rheumatism.

SURGERY.

1. Outline briefly the surgical diseases of the third nerve.
2. Outline the technique of tendon transplantation.
3. Name the structure in which rodent ulcers most commonly develop, and give surgical treatment.
4. Give etiology of delayed fracture union.
5. Outline the best method for male sterilization.
6. Describe the bloodless operation for amputation at the hip.
7. Give etiology and treatment of tenosynovitis.
8. Name five forms of talipes and give attitude of foot in each.
9. Name the principal blood-vessels and nerves, severed in wrist amputation.
10. Under what conditions may a wound be closed without drainage?

ANSWERS.

NEUROLOGY.

1. *Acute ascending paralysis* is an ascending paralysis beginning in the legs, rapidly involving the trunk, diaphragm, arms, and the muscles innervated by the bulb (particularly the muscles of respiration), and so causes death. Its etiology is not settled; it is probably an acute infection of the spinal cord (sometimes including peripheral nerves and the bulb).

2. The *heart is controlled* by: Sympathetic nerves, which accelerate it; by the pneumogastrics, which have an inhibitory influence; probably by a depressor nerve; also by certain intrinsic cardiac ganglia.

3. "The speech areas, four in number and in kind, are in the left hemisphere in righthanded persons and in the right in lefthanded persons. * * * * The motor speech center lies in the posterior part of the third frontal convolution (Broca's convolution), just in front of the center of the muscles of speech (hypoglossal and facial nerve centers). * * * * The power of writing is usually lost with motor speech. The probable location of its cortical center is in the posterior two-thirds of the first, and perhaps in the second, temporal convolution. * * * * The visual speech center lies in the posterior part of the angular gyrus in the outskirts of the higher visual or the visuopsychic field."—(From Woolsey's *Applied Surgical Anatomy.*)

PHYSICAL DIAGNOSIS.

1. *Herpes zoster* is "an acute inflammatory disease, characterized by the development of groups of firm and distended vesicles situated upon inflamed bases corresponding to a definite cutaneous nerve, and accompanied by more or less severe neuralgic pains. The affection begins with neuralgic pains, either of a burning or lightning-like character, with slight febrile phenomena, followed by the appearance of papulovesicles along the tract of pain; these soon become vesicles situated on bright red, highly inflamed bases. The vesicles are about the size of pin-heads, or, perhaps, a little larger; usually discrete, although they frequently coalesce, forming irregular patches, appearing in groups until the third to the fifth or even tenth day, when they gradually desiccate, and at the end of the second week nothing remains except occasionally a slight scar, which may disappear or become permanent. When the eruption is at its height it is perfect in its anatomic formation, each vesicle being well shaped and seated on a bright red, inflamed patch of skin, and distended with a translucent, yellowish fluid. The vesicles show no tendency to rupture spontaneously. In rare instances they may become purulent, hemorrhagic, or gangrenous. The eruption is almost invariably confined to one side of the body, although in rare instances it is seen upon both sides. It is usually found upon well-known nerve-tracts. Recurrence is rare."—(Hughes' *Practice of Medicine.*)

2. *Acute bronchitis* begins with coryza; soreness and tenderness may be behind the sternum; pain may be caused by coughing; expectoration is abundant; dyspnea is in proportion to the extent of the disease; the pulse-respiration ratio is not altered; fever is slight or absent; various rales may be present; the condition is generally bilateral; ends by lysis.

Lobar pneumonia begins with rigors, sometimes also with vomiting; pain on affected side; expectoration is rusty and tenacious; breathing is very rapid; the pulse-respiration ratio is much disturbed; there is considerable fever; crepitant râles are heard in first stage, also in third stage (râle redux); usually only one side is affected; ends by crisis.

3. *High blood pressure* can be determined by the use of a sphygmomanometer; it is found in: Arteriosclerosis, chronic interstitial nephritis, cerebral hemorrhage, uremia, gout, aortic regurgitation, angina pectoris, puerperal eclampsia.

4. *Physical signs of aortic regurgitation:* "*Inspection* shows that the cardiac impulse is forcible and displaced downward and to the left. The pulsation is visible far beyond the normal apex. *Palpation* confirms inspection. It may at times serve to detect a diastolic thrill over the base of the heart and the adjacent large vessels. The Corrigan pulse and the capillary pulse are recognized by palpation. *Percussion* serves to demonstrate an increase in the area of cardiac dullness downward and to the left. Occasionally it is increased upward and to the left of the sternum as the result of hypertrophy of the left auricle. *Auscultation* reveals characteristic alterations in the heart sounds. The first sound is forcible; the second sound is replaced or associated with a churning, rushing, or blowing murmur of low pitch, well heard at the second right costal cartilage (aortic area), but most distinct at the junction of the sternum and the fourth left costal cartilage. It is diastolic in time, and is transmitted downward and toward the apex. A presystolic rumbling murmur (Flint murmur) may occasionally be heard over a limited area at the apex."—Hughes' *Practice of Medicine.*)

5. *Organic murmurs* are due to stenosis or incompetency of one or more of the valves of the heart.

Functional murmurs are not due to valvular disease.

Organic murmurs may be systolic or diastolic; may be accompanied by marked dilatation or hypertrophy, and there will probably be a history of rheumatism or of some other disease capable of producing endocarditis. Whereas a murmur, usually systolic, soft, and blowing, heard best over the pulmonic area, associated with evidences of chlorosis or anemia, and affected by the position of the patient, is a *hemic* or *functional* murmur, and denotes as a rule an impoverished condition of the blood.

OPHTHALMOLOGY AND OTOLOGY.

1. *Trachoma* is an inflammatory condition of the conjunctiva, accompanied by hypertrophy, granule formation, and subsequent cicatricial changes.

In *conjunctivitis* there are no granules with subsequent cicatricial changes.

2. *For chemical burns of the eyeball:* The treatment consists in the complete removal of the caustic substance as soon as possible. Solid particles are removed with cotton or forceps. Then the conjunctival sac is washed out with solutions which tend to neutralize the corrosive substance or render it insoluble. In the case of lime, mortar, or caustic alkalies, we flush out with a solution of boric acid; or we may wash out the eye with oil. If the corrosive agent consisted of an acid, the eye is irrigated with a weak solution of sodium bicarbonate. Subsequently we use cold compresses, atropine, and sometimes a bandage. After the loosening of the eschars, we must separate the adhesions frequently. Symblepharon often occurs notwithstanding the greatest care.—(May's *Diseases of the Eye.*)

3. MASTOIDITIS. "Inflammation of the mastoid cells may be produced by the extension of the disease from the tympanum. Rarely it is due to extension of external inflammation. The symptoms are deep-seated pain (increasing on deep pressure), swelling and tenderness over the mastoid process, accompanied by more or less fever and rapid pulse, coated tongue, anorexia, and malaise. When the periosteum is affected the tissues behind the ear are swollen and the auricle stands out from the head, the canal is smaller and the posterior superior, inner bony wall of the canal droops. If pus has formed, fluctuation may be detected."—(*Cyclopedia of Medicine and Surgery.*) Other causes are: Long exposure to wet or cold, and some of the acute exanthematous diseases. *Possible serious results* are: Thrombus formation in the sigmoid or other sinus, abscess formation in the brain, meningitis, septicemia, pyemia.

PEDIATRICS.

1. *Scarlet fever.* Period of incubation, from a few hours to seven days. Stage of invasion, twenty-four hours. Character of eruption, a scarlet punctate rash, beginning on neck and chest, then covering face and body; desquamation is scaly or in flakes. The eruption is brighter, is on a red background, punctiform, and is more uniform; the temperature is higher, the pulse quicker; the tongue is of the "strawberry" type, the lymphatics in the neck may be swollen, and there is sore throat; Koplik's spots are absent.

Measles. Period of incubation, ten to twelve days. Stage of invasion, four days. Character of eruption, small dark red papules with crescentic borders, beginning on face and rapidly spreading over entire body; desquamation is branny. The eruption is darker, less uniform, more shotty; the temperature is lower, pulse slower, the tongue is not of the "strawberry" type; coryza, coughing, and sneezing may be present; Koplik's spots are present.

2. *Summer diarrhea*, or cholera infantum, is due to the toxins produced by bacteria in milk. Treatment: Ordinary diarrhea should be prevented from terminating in cholera infantum. The stomach and colon should be irrigated. From 3ij-4 of water at 100° F. should be allowed to flow into the stomach through a soft-rubber catheter and be siphoned out. This should be done only once. For the colon, sodium bicarbonate, 3i, should be added to the pint, and the irrigation performed twice daily. If the rectal temperature is very high ice-cold water should be used; otherwise warm water. When symptoms of collapse appear hot pack is used. Ice-water quenches the thirst, even if it is vomited. Champagne and drop-doses of brandy may be given if the stomach is tolerant. Strychnine, gr. 1/100 hypodermically, to a child one year old, is a valuable stimulant. Morphine, gr. 1/100, and atropine, gr. 1/800, may be given in the same way and repeated every hour until the child is quieted—(*Pocket Cyclopedia.*)

PRACTICE.

1. LOBAR PNEUMONIA. *Diagnosis:* (1) From *acute phthisis:* The symptoms and physical signs of *lobar pneumonia* and *acute pneumonic phthisis* may be the same for the first eight or ten days; at this period the fever in *pneumonia* drops by crisis; whereas in *phthisis* the fever continues for some time longer and the patient gets worse; the sputum contains tubercle bacilli and elastic fibers, and instead of retaining the rusty color it becomes purulent and greenish.

In *pneumonia*, the breathing is very rapid, the pulse-respiration rate is disturbed, the fever is usually high, and runs a regular course, crepitant râles are heard at first, then signs of consolidation follow, and crepitant râles again succeed.

In *phthisis*, the breathing is hurried and there is dyspnea, the fever is often high, but does not run a regular course, at first the signs are those of bronchitis, followed by consolidation, a softening, or excavation in different parts of the lungs; sometimes there is nothing to be heard but scattered râles.

(2) From *bronchopneumonia:*

LOBAR PNEUMONIA	BRONCHOPNEUMONIA
Generally a primary disease.	Generally secondary (to bronchitis or an infectious disease).
Age has little influence.	Generally found in very young or very old.
Sudden onset.	Gradual onset.
Fever is high and regular.	Fever is not so high, and is irregular.
Ends by crisis between sixth and tenth day.	Ends by lysis, at no particular date.
Generally only one lung affected.	Generally both lungs affected.
The physical signs are distinct, and there is a large area of consolidation.	Physical signs indistinct, and the evidences of consolidation are indefinite.
Sputum is rusty.	Sputum is rather streaked with blood.

(3) From *acute bronchitis*, see PHYSICAL DIAGNOSIS, question 2.

Treatment: "Consists in rest in bed, milk diet, and the administration of fractional doses of calomel followed by a saline in the early stage. The nervous symptoms and temperature may be controlled by applying ice-bags or compresses wrung out of cold water (60°-70° F.) to the chest or by the use of the warm or cold wet-pack. The heart and pulse should be sustained by the administration of alcohol, strychnine (gr. 1 60-1/20), atropine, caffeine, strophanthus, and nitroglycerin. Digitalis may also be employed. Inhalations of oxygen afford temporary relief when the dyspnea and cyanosis are extreme. In young, vigorous, and plethoric adults, with hyperpyrexia and a high-tension pulse, bleeding may be beneficial in the first 48 hours. Convalescence should be guarded, and tonics, stimulants, etc., will be found very useful in this period of the disease."—(*Pocket Cyclopedia.*)

2. The *chancre* requires local cleanliness. Some preparation of mercury must be given for a long period of time, either by mouth, by inunction, or by hypodermic injection. Salvarsan given either subcutaneously, intravenously, or intramuscularly is the most modern form of treatment.

HYPERTROPHIC CIRRHOSIS.	ATROPHIC CIRRHOSIS.
Jaundice. Early and marked, bile often absent from feces.	Late and slight, bile usually present.
Ascites. Late and unimportant.	May be early; often enormous.
Spleen. Enlarged early and markedly.	Late and less.
Alimentary hemorrhage, piles. Not common.	Common.
Liver. Large, smooth, mottled, green.	Small, rough, pale or yellow.
New fibrous tissue. In fine lines and strands between acini and cells, involving all parts equally.	In broad bands, making prominent islands in which the single acinus may appear nearly normal; distributed irregularly.

3. DIAGNOSIS OF CIRRHOSIS OF THE LIVER. "The characteristics of hepatic cirrhosis are the history, area of liver dullness, symptoms of portal obstruction, jaundice, and the course and termination. The distinction between the two varieties is well given by Thayer in the preceding table:

Atrophy of the liver, or the nutmeg liver, is almost always confounded with cirrhosis; the former occurs most commonly with obstructive diseases of the heart and lungs, and the surface of the organ is not nodulated, nor is there a history of alcoholism.

Cancer and tubercle of the peritoneum have many symptoms akin to cirrhosis. The points of differentiation are great tenderness over abdomen, rapidly-developed ascites, rapid decline in strength and flesh, absence of jaundice, absence of long-continued dyspepsia, absence of hepatic changes on percussion, and the presence of tubercle or cancer deposits in other organs."—(Hughes' *Practice of Medicine.*)

4. *Treatment of la grippe:* "Absolute rest in bed and liquid diet should be prescribed. The administration of fractional doses of calomel (gr. 1/6 every hour for 6 doses) should begin the treatment. Phenacetin, gr. 5 every 3 or 4 hours, may be given for the fever and the pains. Quinine (gr. 4), sodium salicylate (gr. 7), or whiskey (54) may be administered every 3 or 4 hours. The local application of menthol (gr. 1½) in liquid vaselin (℥1) to the nasal mucous membrane is beneficial. Sulphonal (gr. 10) or trional (gr. 15) will relieve insomnia. Iron, quinine, and strychnine are indicated in the convalescence."—(*Pocket Cyclopedia.*)

5. *Treatment of tapeworm:* The patient should be limited to a liquid diet for two days; salines should then be administered; then the oleoresin of aspidium in a dose of one to two drams, followed in a few hours by another saline. The treatment can only be considered successful when the head of the worm is found in the dejecta.

6. Headache "may be due to organic cerebral disease, congestion and anemia of the brain, functional nervous disorders, toxemic conditions, derangements of the stomach and liver, and reflex causes, such as eye-strain, nasal disease, etc. The *treatment* should be directed to the cause. Eye-strain should be sought for and corrected, as well as any existing nasal disease. Toxemic states should be remedied by dietary and medicinal prescriptions. Anemia calls for preparations of iron. Uterine disease should be corrected. Cerebral syphilis demands mercurials and iodides. Preparations containing citrated caffeine, monobromated camphor, acetanilid, phenacetin, etc., may be given during the attack. For nervous headaches, a pill containing zinc phosphide (gr. 1/10) and extract of nux vomica (gr. 1/3) may be administered. Palliative treatment consists in local applications of cold, evaporating lotions, menthol, thymol. Various pungent and aromatic spirits are useful for inhalation."—(*Pocket Cyclopedia.*)

7. *Treatment of constipation:* The cultivation of a regular habit is essential; fruit, vegetables, and substances which leave a residue should form part of the diet; castor oil, or cascara, or calomel or a saline or an injection of water or oil may be tried, but drugs should be dispensed with as long as possible; exercise or massage may be beneficial; fats or olive oil may be taken; the pill of aloin, belladonna and strychnine may be tried.

8. LOCOMOTOR ATAXIA. *Etiology:* It is a disease of adult life; is more common in men than in women; is more common in cities than in the country; syphilis is believed to be the most frequent direct cause; alcoholism, injury, exposure to cold and wet, have all been urged as causes, but they are not now assigned so important a place as etiological factors as was formerly the case.

Symptom: Loss of coordination; characteristic and unsteady gait; tendency to stagger when standing up with feet together and eyes closed; sharp and paroxysmal pain, called *crises;* girdle sensation; loss of knee-jerk and other reflexes; Argyll-Robertson pupil.

Prognosis is unfavorable; the disease is chronic, but may remit for a period; death by some intercurrent affection may occur.

Treatment consists of rest in bed for long periods, absence of excitement, nutritious food, cod liver oil, tonics, silver nitrate, massage, systematic exercises, counterirritation, and analgesics.

9. In *endocarditis:* The murmur is soft, not harsh; it is systolic or diastolic; it may be transmitted; it is heard loudest at definite points; it is not followed by signs of effusion; the apex beat may be strong.

In *pericarditis:* The murmur is harsh; is not in connection with the heart sounds; is heard loudest at the base of the heart and over the precordium; is followed by (or accompanied with) signs of effusion; the apex beat is generally feeble.

Some of the causes of endocarditis are: Acute articular rheumatism, chorea, tonsillitis, scarlet fever, pneumonia, cancer, gout, diabetes mellitus, Bright's disease, septicemia, gonorrhea.

Treatment of endocarditis: "All forms of endocarditis require absolute rest, which should be prolonged for weeks or even months. The primary disease should be treated. Overstimulation of the heart must be avoided, and it is in acute endocarditis that most harm is likely to be done by the indiscriminate use of digitalis, though it may be called for if the heart is failing. Rest, light diet, milk while fever is present, attention to the bowels and to sleep, form the best treatment of simple endocarditis. The malignant form should be treated like septicemia. If the organism can be isolated from the blood, antistreptococcic serum or a vaccine may be tried, but under any treatment most cases have a fatal ending."—(Wheeler and Jack's *Handbook of Medicine.*)

10. CHRONIC RHEUMATISM. *Cause:* "The disease is most common among the middle-aged poor, particularly those who are exposed to cold and wet. Very rarely it follows acute rheumatism." *Treatment.*—"Internal medication is unsatisfactory. Guaiacum, iodide of potassium, and arsenic are recommended, but the salicylates are ineffectual. Local measures, such as counterirritation, massage, passive movement, and hydrotherapy are much more useful. Obstinately painful nodules may be excised. A course of baths, and a warm winter climate may be of great service in cases where such measures are possible."—(Wheeler and Jack's *Handbook of Medicine.*)

SURGERY.

1. *Surgical diseases of the third nerve:* "One or more of the branches of this nerve may be compressed by extravasated blood, or be contused and lacerated in fractures implicating the region of the sphenoidal fissure. Tumors and aneurysms growing in this region also may press upon the nerve. Sometimes both nerves are involved; for example, in fractures involving both sides of the anterior fossa, and in tumors, particularly gummata, growing in the region of the floor of the third ventricle. In lesions of the cerebral hemispheres the third nerve is very frequently paralyzed. Its cortical center lies in close proximity to the center for the face. The most prominent symptoms of complete paralysis are ptosis or drooping of the upper eyelid, external strabismus, and slight downward rotation of the eye. There is also dilatation of the pupil from paralysis of the circular fibers of the iris, and loss of accommodation from paralysis of the ciliary muscle. Paralysis of the muscles supplied by the third nerve is frequently associated with paralysis of other ocular muscles. When all the muscles of the eye are paralyzed, the condition is known as "ophthalmoplegia externa"; it is usually due to syphilitic disease in the floor of the third ventricle."—(Thomson and Miles' *Manual of Surgery.*)

2. *Tendon transplantation:* "This operation consists in altering the attachments of the tendons of healthy muscles so as to have them fulfil the functions of those which are paralyzed. Four methods of transplantation are practised: first, the tendon of the healthy muscle may be completely divided and the upper end sutured to the paralyzed tendon; second, the tendon of the paralyzed muscle may be divided and the lower end sutured to the healthy one; third, the tendon of the sound muscle may be split, one end remaining attached to its normal insertion, and the other sutured to the paralyzed tendon; fourth, a portion or the whole of the healthy tendon may be implanted subperiosteally at the desired point, instead of stitching it to the paralyzed tendon."—(Wharton's *Minor Surgery.*)

3. The structure in which *rodent ulcer* most commonly develops is the sebaceous glands of the skin. Surgical treatment consists of free removal with a good margin all around the ulcer; if this is not practicable the Roentgen rays may be tried.

4. *Delayed union in fracture is caused by:* Ill health, want of approximation of the end of the bone, want of blood supply in the bone, defective innervation of the bone, disease of the bone, lack of rest, and immobility.

5. To accomplish *male sterilization* a partial vasectomy may be performed. The skin and fascia are incised, the spermatic cord is exposed just below the external abdominal ring, the vas is separated, and two ligatures are placed around it about ¾ inch apart; half an inch of this part is excised, and the wound is closed with ligatures.

6. *Bloodless operation for amputation at the hip:* "The most satisfactory method in the great majority of cases is Wyeth's, in which a constrictor is held in place by the preliminary passage of two steel pins. The outer pin is inserted an inch and a half below and a little internal to the anterior superior spine of the ilium, and is brought out just back of the great trochanter. The inner pin is entered one inch below the level of the crotch and internal to the saphenous opening, and it emerges an inch and a half in front of the tuberosity of the ischium. A sterile cork is pushed on the end of each pin, to save the surgeon from wounding himself from the sharp points. After the limb has been emptied of blood by holding it in a vertical position for five minutes and stroking it from the periphery toward the body, the constricting band is fastened about the limb above the pins. After the passage of the pins and the application of the band of the Esmarch apparatus, the amputation is proceeded with. The hip is brought well over the edge of the table, a circular incision is made down to the deep fascia, six inches below the constricting band, and is joined by a longitudinal skin-cut reaching from the band to the level of the circular incision, and the cuff is reflected to the level of the lesser trochanter. The muscles are cut by a circular sweep at the level of the retracted cuff, the capsule of the hip-joint is opened freely, the cotyloid ligament is cut posteriorly, the thigh is bent upward, forward, and inward to dislocate the head of the bone, and, using the thigh as a handle, the round ligament is incised and the limb removed. After ligating the vessels and introducing drainage tubes the flaps are sewn together vertically."—(Da Costa's *Modern Surgery.*)

7. TENOSYNOVITIS. *Etiology:* Strain, sprain, overuse, wounds, infection, tuberculosis, inflammation. *Treatment:* Rest, hot fomentations, massage, counterirritation, rupture by pressure, incision, excision.

8. (1) *Talipes varus*, in which the inner edge of the foot is drawn up, the anterior two-thirds is twisted inward, and the outer edge rests on the ground.

(2) *Talipes valgus*, in which the outer edge of the foot is drawn upward, and the inner side of the foot and ankle rest on the ground. This condition is the reverse of *talipes varus.*

(3) *Talipes equinus*, in which the heel is raised and cannot be brought to the ground, and the patient walks on the toes and on the distal ends of the metatarsal bones.

(4) *Talipes calcaneus*, in which the toes are raised and the heel depressed, so that the patient walks on the latter. This condition is the reverse of *talipes equinus.*

(5) *Talipes equinovarus*, in which the heel cannot be brought to the ground, and the patient walks on the outer margin of the sole.

9. In *wrist-amputation* the following *blood vessels and nerves are severed:* Radial, ulnar, superficial volar, dorsalis indicis, and radialis indicis arteries; and median, radial, and ulnar nerves.

10. A *wound may be closed* when there is no severe hemorrhage, no foreign bodies present, and when the wound is not infected.

BULLETIN OF APPROACHING EXAMINATIONS

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION †	
Alabama*	W. H. Sanders, Montgomery	Montgomery	Jan. 12
Arizona*	J. W. Thomas, Phoenix	Phoenix	
Arkansas	W. S. Stewart, Pine Bluff	Little Rock	Nov. 10
California	C. B. Pinkham, Sacramento	Los Angeles	Dec. 8

Miscellany.

Front Wheel Brakes.—H. Massac Buist states that front wheel brakes prove a saving of tires in relation to the actual amount of braking work done. At the recent Grand Prix race on the Lyons circuit it was noted that the cars that had front wheel brakes would rush up to the corners with the accelerator pedal full down for anything from fifty to seventy yards after those with brakes working on the back wheels only had applied them to those wheels. Therefore the total amount of braking effort on the cars with four wheel brakes was, of course, vastly in excess of those with two, because the machines were slowed in about half the distance. The demonstration of the use of front wheel brakes was remarkable. It should be appreciated that the moment braking is applied to the front wheels the result is to throw weight forward on to these wheels, thereby increasing their power of adhesion to the road surface, and accordingly preventing the wheels locking and skidding. It is skidding that destroys tires and reduces braking effort to its least possible value. A natural physical law assists those who desire to employ the principle of brakes on all four wheels. One result of the race will be to give a big impetus to the employment of front wheel brakes for touring cars. But the medical man must be warned that it is one thing to want to have brakes on the front wheels and quite another so to scheme them that they shall prove a blessing instead of a bane.—*British Medical Journal.*

The Value of Avocations.—A. Stuart M. Chisholm notes that specialization, while impoverishing the individual, has enriched the profession. There are many diversions which enable men who are engrossed in their professional work to counteract its narrowing influences and at the same time to provide a needed relaxation. Collateral and subordinate pursuits provide an enlarged scope, open up whole spheres of personal culture, and widen the horizon of life. The specialist may, without prejudice to his art, emulate the example of Prospero in laying down at times his conjurer's wand and taking off his magician's mantle, while he devotes a period of his time to his greater personal needs and looks abroad over the world with opened eyes.—"Recreations of a Physician."

Tobacco and War.—The *Lancet* entertains the hope that England's fighting men will be generously supplied with the weed that brings solace and joy when the nervous system is in a ceaseless state of tension from dangers and excitement. Tobacco fills an important place in the psychophysiological affairs of the race, and the habit of smoking, if over-indulgence be avoided, does something to temper the intensity of the struggle.

Ambidexterity.—H. MacNaughton-Jones states that in 1868 when he was engaged in operative surgery on the eye he realized the great disadvantage of not being able to use his left hand equally with his right. He overcame this difficulty, but found that when tired from overwork he could not trust his left hand. In obstetric practice he learned the truth of the aphoristic teaching of the late Dr. Robert Barnes "that every obstetrician should learn to shave himself with his left hand." As a boy at college, MacNaughton-Jones owed his superiority as a handball player to his ambidexterity and this capacity made him an expert in the use of the gloves.—"Ambidexterity and Mental Culture."

THE RELATION OF DIET TO CANCER.*

BY L. DUNCAN BULKLEY, A.M., M.D.,

NEW YORK.

PHYSICIAN TO THE NEW YORK SKIN AND CANCER HOSPITAL, ETC.

THAT deaths from cancer are certainly on the steady increase in this and other countries has been abundantly shown by statistics, which need not be quoted here. That the evident increase of cancer is not wholly or even largely due to more accurate diagnosis and public attention to the disease is admitted by all who have given due consideration to the subject; that thus far practically nothing has been accomplished in the way of checking the extension of cancer is also a matter of general knowledge; and all this in spite of the earnest and faithful work of innumerable research workers, and the expenditure of vast sums of money.

It is proposed here to make a brief review of the present position of the question involved, to examine some of the facts concerning malignant disease, and to inquire if sufficient attention has been paid to a certain element which so largely concerns the health and well-being of the individual, and the structure and growth of normal and abnormal tissues, namely, diet.

There must, of course, be some reason for the increase of cancer, and earnest work should still be given to searching most diligently for the cause of the disease, in the laboratory as well as in practice, even though as yet there have been relatively little result.

Parasitism has been excluded, for while in some animals inoculation experiments have resulted in the transmission of certain tumors, little has been determined except that the tumor cell when transplanted can induce the neighboring tissue cells to take on a similar aberrant action, which may result in the formation of a malignant tumor. The same occurs in metastasis in cancer patients. But this does not at all explain the true nature of cancer, nor its development in those who have had no connection with other patients so afflicted. On the other hand, the instances of suggested or supposed human transmission of cancer from one person to another are so remarkably few, and often so exceedingly doubtful, that the question of its contagiousness has also been excluded, certainly in the sense in which this term is applied to other affections. It has been found impossible to inoculate human cancer into rats, mice, and apes, or to inoculate animal tumors into animals of different species.

Heredity has been advanced as a cause, but statistics fail to verify this in any degree whatever. In former years malaria was believed to have an influence, and one investigator thought to trace the prevalence of cancer to telluric influence, showing a preponderance of cases along certain water courses; syphilis, in its latent effects, has also been claimed as an element in the causation of cancer; but all these and many other etiological propositions are no longer considered to be tenable, and the very multiplicity of suggested causes shows that we are yet far from the true etiology of cancer.

More recent scientific study has attempted to show that cancer originates from what is called "embryonic rests," or prenatal, wrongly placed tissue elements, which at some time or other take on morbid action and develop into what we know as the various forms of cancer. But here again it is necessary to determine what causes them at certain times and in certain places thus to proliferate and form new tissue, which then becomes malignant and may proceed to destroy all contiguous tissues, and even to cause death. It has been claimed by many that local injury is the cause which determines the activity of the misplaced cells, and starts them on their disastrous or rampant course. While this appears to be the case in certain instances, it is far from proven to be always so, nor does it in any way explain the persistency with which malignant disease, when once started, pursues its destructive and even fatal career, with a great tendency to recurrence, either in the former site or at some distant focus, through the agency of the lymphatic or vascular system.

On the basis of the embryonic theory surgeons have of late most earnestly advocated the very early and complete removal of malignant lesions, including those of suspected malignancy, and even many innocent lesions which are observed occasionally to lead to cancerous formation; and with our present knowledge this cannot be urged too strongly. But while this has improved operative statistics it has not contributed much to our real knowledge of the basic cause of cancer, nor has it taught us why these lesions, or "embryonic rests," will remain quiescent or prove harmless in some individuals, while in others they are most formidable agents of destruction. For it is now recognized that these are most common anatomical or histological accidents, indeed it is claimed that they occur in every individual.

The same is true of the many and various forms of treatment other than surgical excision, such as deep acting caustics, and even the *x*-ray and radium, which, like surgery, only remove the *products of disease* and the focus of possible systemic infection, and do not affect the basic cause of the complaint; this latter recent scientific investigation and observation are showing more and more to be associated with metabolic or chemico-physiological changes in the system. All this leads thoughtful persons to inquire if there is not some deeper, fundamental cause lying back of the trouble, which

*Read before the Section on Pathology and Physiology, American Medical Association, June 25, 1914.

should be reached and rectified by medical skill and acumen.

It is recognized by all that the tissues develop and are maintained by nutrition derived from the food and drink taken, and tumors all certainly grow by the same means. For years it has been claimed by one person after another that diet has more or less influence in the production of cancer, and even over one hundred years ago Howard, Lambe, and others adduced strong proof to show the effect of diet in curing certain cases of undoubted cancer of the breast and uterus, the diagnosis of which was confirmed by prominent surgeons of the day.

It has been pretty clearly demonstrated that cancer is a disease of civilization, increasing among those peoples who had previously been free from it, in proportion as they become associated with those who are more highly civilized, and as they have adopted their customs, and manner of life, and diet; this has been shown in regard to negroes before and after the Civil War, and also as to primitive people in India, Australia, Africa, Mexico, Brazil, etc.

With advancing civilization the diet has become more and more complicated, and luxury and over eating have increased: this is especially true of meat eating, and alcohol and coffee drinking. The increase in the consumption of meat has been startling in many localities, and in England it has reached a yearly total of 130 pounds per capita for men, women, and children, in addition to large quantities of fish, game, poultry, rabbits, eggs, cheese, etc. Among the well-to-do the meat consumption has been estimated at between 180 and 330 pounds per year: all this is much more than double the amount consumed fifty years ago, and in the same time the deaths from cancer have increased over *fourfold*.

The same figures apply roughly to the United States, where the per capita meat consumption is said to be considerably in excess of the European average, and all statistics show that cancer is rapidly increasing in this country. In a recent Bulletin of the Board of Health of New York City the following statements are made in regard to the mortality from cancer in 1913: "The statistics of our seven largest cities recently tabulated, show that in that year the cancer death rate was the highest on record. For New York City the rate was 82 per 100,000 of the population, against an average of 79 for the last five years; for Boston 118, against an average of 110; for Pittsburgh 79, against an average of 70; for Baltimore 105, against an average of 94; for Chicago 86, against an average of 81; for Philadelphia 95, against an average of 88; for St. Louis 95, against an average of 85." This average increase of over 8 per cent. of deaths from cancer in the combined population of these seven cities during the last five years is certainly an alarming fact, and cannot be explained on the ground of greater accuracy of diagnosis; for it is not to be presumed that there has been such great improvement along these lines during the single year 1913. It has been shown that with the same rate of increase of deaths from cancer, unless there be found some way to check its production, the death rate at the end of the century will be appalling.

In striking contrast to the enormous extent and increase of cancer in meat-eating communities may be mentioned the relative rarity or almost absence of the disease in regions where the diet is largely confined to the products of the ground. Williams[1] has collected from all sources the greatest amount of evidence that cancer is relatively rare, and often really unknown, as reported by competent observers, among various aborigines in the interior of many countries, who live on the products of the vegetable kingdom, with little if any meat secured in hunting.

Is it not possible and even probable that the relatively less increase in cancer in New York City during the last five years is in part due to dietary causes? Thus in 1913 the death rate was 82 per 100,000, against 79 for the average of the preceding five years, while the highest increase was in Baltimore, 105 against 94, or 11 per 100,000 to 3 in New York City. It is known that we here, in New York City, have vast hordes of foreigners, many newly landed, who still live as at home, and are too poor to buy much meat. The Italians still live on macaroni, and cereals form a large part of the diet of those from southern Europe, etc. etc. During a rather extensive trip through the Far East I was unable to see or even hear of any cancer, although I met a large number of medical men and made inquiry regarding the same, and visited hospitals with a total of many thousands of patients; in Japan, Korea, China, the Philippines, India, Siam, and Egypt I met the same response, that cancer was rarely seen among those vegetarian peoples.

Cancer has repeatedly been observed to disappear spontaneously, and many such cases are on record by careful and competent medical men: in certain of these instances it has occurred in connection with a radical change in the mode of life and diet, but in the majority of instances there is no record of the special cause of its disappearance. But the lesson to be learned from this is that there are conditions of the system which are antagonistic to the abnormal proliferation of cell tissue, even when it has begun to take place, as we must believe that there are conditions of the system which favor such diseased action of aberrant cells. An interesting confirmation of this is attributed to Ehrlich, but I cannot find the original reference. He "has shown that mice living upon a rice diet cannot be inoculated with cancer, while mice living on a meat diet can be readily inoculated, cancerous tumors developing quickly and continuing to grow until the animal dies. Ehrlich also found that when mice with cancerous tumors, the result of inoculation, were placed upon a rice diet, the tumors ceased to grow and in many cases degenerated and disappeared." Interesting confirmation of this has been given by Sweet, Corson, White, and Saxon.[2] They found that 75 per cent. of 75 mice developed experimentally inoculated tumors when under normal diet, while only 19 per cent. of 75 other mice developed such tumors when under a diet of glutenin and gliadin, that is vegetable proteins; also that the tumors in the latter were in thirty days hardly larger than in the former in ten days.

Psoriasis furnishes an illustration which may be of service in understanding the relation of diet to cancer; for psoriasis is characterized by a disordered epithelial growth, which both shows on the surface and manifests itself by epithelial prolongations into the corium, which are quite comparable to the ingrowing cellular masses of early cancer; moreover it is not so very rare to have epithelioma develop from lesions of psoriasis.

The real cause of psoriasis has not as yet been

established, but there is abundant testimony to show that the eruption is intimately connected with faulty nitrogenous metabolism, or rather with the presence of an excess of nitrogenous matter in the system. For many years the present writer has adduced proof of this relationship, and has reported a number of cases, confirmed by other practitioners, where the lesions of psoriasis have entirely disappeared, simply under an absolutely strict vegetarian diet, excluding also coffee and alcohol, without the use of any medical treatment whatever, internal or external; he has also many patients in private practice who remain free from eruption while strictly faithful to the same diet, and many others who relapse again and again when the diet is relaxed, and again lose the eruption under rigid vegetarian diet. All this has been confirmed by other observers, and very strikingly so by Dr. Schamberg,[3] who made some very careful laboratory observations in connection with the Philadelphia Polyclinic, on nine psoriasic patients. From his studies he concluded that these patients possess a strong tendency to store nitrogen, and that on a high protein diet tremendous quantities of nitrogen may be retained in the system; he also confirmed the injurious effects of a strong nitrogenous diet, and the disappearance of the eruption under vegetarian diet. We are as yet quite in the dark as to why various disturbances in regard to nitrogenous and other metabolism take place in the body of these patients, as we are of the reasons of gouty and diabetic disorders, but clinical facts often lead the way to pathological discoveries, and those in regard to psoriasis are instructive and suggestive in our present study; and such researches are much needed in regard to the metabolism of cancer patients before the development of the disease, or in its early stages, although considerable work has already been done in connection with the chemico-pathology of advanced cancer.

There is an analogy to be found between what has been previously mentioned in connection with the natural history of cancer, as to its increase in connection with the greater consumption of meat, and what has just been detailed in regard to psoriasis. While to a superficial observer there may not seem to be any very great connection between the two diseases, there is in reality a lesson to be learned from the one to the other. In both we have perverted and active proliferation of epithelial cells, and inasmuch as cell growth depends upon protein, we have with an excessive nitrogenous intake, or a retention of nitrogenous elements, an augmentation of the eruption of psoriasis, even as we have seen cancer increase with the increased consumption of meat. And, just as psoriasis has been observed by many to disappear when the nitrogenous supply was cut off, so numerous observers, and the present writer among them, have seen unquestioned cancer steadily retrogress and even disappear, and remain absent, under a strictly non-nitrogenous diet.

For very many years I have held the view that meat eating was productive of cancer and have treated very many cases, of both recurrent and primary cancer, with an absolutely vegetarian diet, with results in some cases which were remarkable and most gratifying. But I have hesitated writing strongly on the subject before lest I should be misunderstood or misjudged, as in such cases reliance has to be placed on a clinical diagnosis (always verified by others), while results claimed are always open to question by some. I have also feared lest I might really do harm by advocating a medical consideration and treatment of cancer, since thereby some might be led to neglect operative measures in proper cases, at the proper time; and so in certain instances great injury and injustice might be done to the patient, and the time pass in which a surgical operation might possibly be of service.

I wish, therefore, to repeat what I said before, that with our present knowledge competent surgical interference cannot be urged too early or too strongly in suitable cases; but I wish also to enter my strong protest against the course which is usually followed in regard to cancer, both before and after operation. With a rather extended experience, during the last forty years I have almost yet to find a case which has received adequate and continuous medical care before operation, with a view of discovering and rectifying the cause of the morbid growth. Too often when a cancer is suspected or discovered it is taken as a foregone conclusion that the malady is hopeless, except as the *results of the disease*, that is the new growth, may be removed by the knife, *x*-ray, radium, caustics, etc. And after a surgical operation, as far as my observation goes, the patients are invariably left entirely to their own resources, with the hope that the tumor will not regrow, but with no attempt so to guide the life that there shall not be the tendency to a recurrent malignant new formation.

The limits of the present paper will not admit of a full discussion of the problems of metabolism and chemico-pathology which may and often have to do with this tendency to misgrowth of tissue, concerning which there have been some interesting and valuable researches which are of practical importance in regard to the prevention of cancer, but brief mention may be made of a few points.

Ross[4] has satisfied himself that there is a failure in the potash element in patients who are subject to cancer, and for many years he has administered one of the salts of this mineral in large quantities, both to those threatened with the disease and even in advanced cases, with most satisfactory results. This I can verify fully, and for very many years I have given the acetate of potassium to a large number of patients thus afflicted, and am confident that it has had a large share in producing the benefit that has been observed. Ross calls attention to the errors which exist in regard to the cooking of vegetables, whereby the natural salts are extracted in the water in which they are cooked, which is then thrown away; among the aboriginal natives who are vegetarians, who escape the disease, it is stated that they consume also the water in which vegetable substances are cooked. This waste of the natural salts is especially seen in connection with the cooking of potatoes. These are commonly peeled before being boiled, and by this means the inner skin, rich in salts, is necessarily removed, and the exposed starchy matter is then further devitalized by the water in which they are boiled; they should be boiled in their skins, and it is even better to eat the skins as well, although their outer coating may then be easily stripped off, leaving the inner skin, containing abundance of potash and other salts. Ross adduces much proof in regard to the error in equilibrium in regard to potash salts in those tending to cancer, which cannot be detailed here, but is worthy of serious consideration.

Time fails even to allude to the various studies which have been made in regard to the many alterations in metabolism which have been observed

in cancer patients, all however showing that there is a basic cause for the remarkable and virulent action which certain cells of the body may take on and continue, exciting the same diseased condition in contiguous cells, because they also are bathed in the same deranged blood stream.

Why in some individuals a disturbed nitrogenous equilibrium resulting in cancer occurs, while so many escape, remains still an unanswered question, like so many problems in medicine. Chemico-physiology and pathology are yet in their infancy, and the mysteries of anabolism and catabolism are great, but that they and the action of all the cells composing the organism are under the influence of diet is beyond question. It is also certain that various other causes, such as mental and physical overstrain, etc., can produce such a derangement of the vital organs of the body that disturbed metabolism follows, and that a diet which at one time or in one individual is well borne, at another time or in another individual produces disease. Accumulated evidence, dating back many, many years, points to excessive nitrogenous intake, together with faulty cooking, incident to a more refined civilization, so-called, as a prolific cause for the development of cancer, while an absolutely vegetarian diet, with the exclusion of coffee and alcohol, in conjunction with proper medicinal measures, has repeatedly resulted in the disappearance of cancer. The length of this paper prevents the presentation of illustrative cases which have occurred in my practice during the last forty years, some of the subjects remaining entirely well for ten or more years thereafter.

The medical treatment of these cases along lines of eliminative and constructive therapy, undoubtedly contributed toward the favorable results, but unaided by dietary measures these would certainly have been entirely ineffective.

AMPUTATIONS.

By A. M. Fauntleroy,
Surgeon, U. S. Navy.

The surgical attitude towards the removal of limbs has undergone a great change in the recent past, and within a decade experience has so completely reversed the teachings in regard to certain hitherto accepted procedures that amputations can no longer be considered a beginner's task but has reached the proportion of an art. As Professor Oskar Witzel of Dusseldorf says, "in emergency cases every physician must be able to perform this operation at once, if necessary to save life, but otherwise it demands the highest surgical skill, both in determining the indication and in the proper execution."

In preantiseptic times, and during the time when aseptic surgery was being developed, an injured member usually received short shift at the hands of the surgeon, for the reason that the means of combatting and handling the dreaded infection had not been perfected to the extent they have to-day and the surgeon was thus forced to adopt measures which, in the light of our present knowledge, seem altogether too harsh and heroic. Amputation has become much more rare in the surgery of peace, and its use has been restricted considerably in war, by the recognition of tried and proven methods to conserve to the utmost every portion of an injured member until forced to remove a part in order to save life. The present day surgery makes it possible to wait longer in treating lesions in order to determine what is destroyed beyond repair and what may possibly recover. What appeared formerly to be beyond hope of redemption can now be preserved, and it is no longer a menace to life to adopt an ultra conservative attitude in regard to the time and extent of removal.

The indications for amputation in modern practice have been very much restricted by reviving Lister's "let alone" method in the treatment of wounds, and by the recent advances in bloodvessel surgery, suture, anastomosis and transplantation, through the efforts of such workers as Carrel and Guthrie. When the vitality of a part is threatened and the blood supply depleted, whether from trauma or the gradual occlusion of vessels resulting in gangrene, the anastomosis of large arteries and veins or the transplantation of a segment of vein to complete the continuity of an injured artery will often reestablish normal vitality and enable the parts to live till restoration occurs. It is true that blood vessel work is only successful in skillful and practised hands, but the time may not be far distant when it may come to be more easily practicable and hence should be borne in mind as a factor not to be neglected when possible to apply.

When acute and chronic inflammation has to be dealt with Bier has given us an invaluable remedy, in his hyperemic treatment, to combat this fearsome complication which enables us to bring Nature's valuable forces to the rescue and thus very often save a useful member. Certain deformities, whether congenital or acquired, such as ankylosed joints, flail joints from bony non-union, great destruction of bone from disease or injury, are now successfully treated by either the formation of a new joint through fascia transplantation after the method of Murphy, or the transplantation of large or small pieces of bone to fill up the gap in the bony continuity of a part and fixed in position by means of wiring, plating, nailing, and splinting. Our ideas in regard to tumor growth as an indication for amputation are now undergoing a revision, especially with reference to benign tumors, where resections are now indicated; while even in myelogenous sarcoma plastic operations and transplantations can be made to take the place of removed parts. Roentgenotherapy is also a powerful assistant in regard to limiting mutilation with reference to tumors which heretofore have been regarded as an indication for immediate amputation, and especially has this held good for periosteal sarcoma of the extremities. Having met the modern demands with reference to the changes in the indications for amputation we now pass on to discuss the modern technique and its recent changes.

When once the indication for amputation has been established every effort should be made to increase the patient's general resistance against the depressing effect of the operation. In case of emergency work the means of strengthening the resistance would be limited to an energetic treatment of shock, so that when the patient is placed on the

operation table there should never be a doubt as to his being able to recover from the effects of the operation. Here the indications are such stimulants as brandy, ether, atropin, morphin, infusion of salt solution or transfusion of blood, depending on the condition of shock and its usual attendant loss of blood. Where the operation can be postponed the preparation may take days or even weeks to increase the resisting powers of the patient up to the point where the operation per se will not jeopardize life. Certain it is, as Witzel remarks, "that the mortality caused from the amputation itself must be absolutely excluded and where the case is known to be a hopeless one the operation should never be attempted." The examination of the patient prior to operation should be as careful as is consistent with the demands of the case; the condition of the blood, kidneys, and other vital organs should never be overlooked and, both before and during the operation, the application of Crile's anoci-association principle should always be resorted to.

Of almost equal importance to the saving of life is the modern treatment with reference to the stump. The technique should be such as to always insure a painless, mobile, and useful stump, as there is no more permanent or distressing monument to surgical error than for a patient to be condemned to suffer continuous neuralgias, or to be the possessor of an immobile or nonsupporting, useless stump. The operation should be so planned and executed as to accomplish not only perfect freedom from stump pain, but the later use of an artificial member should receive the surgeon's technical attention at the time of operation and thus guarantee to the patient a strong, supporting, useful stump.

The first step in any amputation is to provide for the arrest of hemorrhage and, this accomplished, the planning of the flaps to conserve the length and strength and supporting character of the member is next to be considered.

The methods for securing bloodless amputations are fully and accurately described in modern text-books and include the use of the time honored Esmarch principle of broad rubber bandage and tourniquet; Wyeth's pins, used in conjunction with a constrictor, in shoulder and hip-joint amputations; the ligating of the principal arteries beforehand; the Lynn-Thomas compressing forceps; the Senn, Larry, Dupuytren, and Kocher methods of controlling hemorrhage in special situations; all of which can be easily worked out on the cadaver.

The question of flap formation is to be considered from several points of view. The formation of the classical flaps as indicated in text-books, while most convenient to illustrate basic principles, can rarely be used without modification to suit individual cases and should be considered only in the nature of types to be followed in principle along general lines. The circular, modified circular, lateral, and anteroposterior flaps are fully described in text-books and should be thoroughly mastered as a guide for general application. The character of the injury, resulting in the destruction of tissue, will largely determine the nature of the flaps to be used. Where age is a determining factor it is to be noted that young tissues are capable of much more plasticity than old tissues which demand simple junction for good union. The question of blood supply, both in quantity and quality, is highly important. The latter is to be considered when such diseases as diabetes or arteriosclerosis are present, and the former is to be considered with reference to the anatomical position of the blood vessels supplying the part. Witzel aptly remarks that "the chief condition for complicated operations is to have the entire region in an aseptic condition. An infection that could not be removed beforehand demands simple procedures."

It is essential that the operation should be so planned that the resultant scar from flap union should never be subject to pressure. The flaps should always be of sufficient length to allow for subsequent muscular contraction, with resultant tension on the sutures, and the separation of the soft parts must be done smoothly with a sharp knife, avoiding handling or contusing of the tissues as much as possible. The so-called "dead spaces" are to be obliterated by the use of buried sutures in coapting the deeper tissues. Where we can be sure of our asepsis the suture and ligature material can be either of the absorbable or non-absorbable variety, but when future infection of the wound has to be considered the more absorbable material is far better in that it does not remain long as a foreign body to cause irritation and a prolongation of the infective process. Careful attention should be paid to the complete arrest of hemorrhage, by ligation of the larger and smaller vessels, torsion of the smaller branches, with manual compression and the application of hot salt solution compresses to control oozing.

Primary union is probably more important in an amputation wound than elsewhere on account of the future function of the stump. In this connection drainage is to be provided to carry off the subsequent extravasation of blood and lymph in order to leave no culture media in the wound for infective organisms. The drainage should be removed at the earliest possible moment, usually the second day, to accelerate primary union in the openings left by the removal of the drainage tubes. The part should be splinted to secure complete rest and the dressings disturbed as little as possible. Nothing, except infection, so interferes with primary union as interrupting the rest of the part involved in the healing process.

We have now to consider the very important feature of producing stumps of the highest usefulness, which takes into consideration painful or tender stumps, mobile stumps, and weight-bearing stumps, all of which means that the surgeon's work is but poorly accomplished if he has neglected to consider these highly important factors in securing a thoroughly useful stump.

A good many text-books still speak of a painful stump as being due to the formation of the so-called "amputation neuromas." It has been repeatedly shown that the amputation neuromas, which are the small terminal knobs of the bisected nerves, are but the result of an abortive effort on the part of nature to regenerate the lost part of the nerve towards the periphery. This attempt at regeneration happens frequently and, as Witzel remarks, if these knobs or terminl neuromas are always to be regarded as the cause of amputation neuralgia, or stump pain, then we ought to cease operating. The cause, however, of this distressing symptom is not the amputation neuroma, as formerly taught, but *is due to the fixation of the nerve to the scar formed in the soft parts and of the latter scar to the bone.* It can thus be readily understood that the stump gradually becomes the seat of tenderness and pain through irritation of the nerve trunks, which are incorporated in the scar, by reason of muscular

flexion and extension. The pain is increased by pressure on the nerve ends imprisoned in the scar tissue, thus making it impossible to produce a weight-bearing stump.

How are we to avoid this most undesirable complication? The answer to this is to recognize the physiological necessity that all nerves should be perfectly mobile in their sheaths, a fact which does not obtain when nerve trunks are fixed in a scar and the resultant ascending perineuritis prevents the nerve from making sufficient excursion in its sheath. The cuneiform or wedge-shaped excision of the bisected nerve end, with subsequent very fine suture of the perineurium, may prevent the formation of knobs at the cut ends of the nerves, but will have no influence on the actual cause of amputation neuralgia, which latter is due to the fixation of the nerve trunk in the scar. *This latter can be avoided, and amputation neuralgia prevented, by seeking out the bisected nerve trunks at the time of operation and pulling them strongly out for a distance of three or four inches and cutting them off smoothly with a sharp knife.* The end of the nerve now slips far back into the layer of connective tissue, out of the way of subsequent scar formation and later glides to and fro in its sheath when the stump is moved by muscular contractions. There is also no pain when the soft parts are shifted or pulled at or pressed against the end of the bone.

There are several other points in connection with sensitive stumps which recent investigation has proven of considerable importance. The question of limiting the osseous scar formation at the end of the stump has been investigated by Bunge, who has shown that if the terminal bone marrow is removed with a spoon in diaphyseal amputation, and at the same time if a periosteal cuff at the end of the bone is removed, the mushroom-like osseous outgrowth at the end of the bone is prevented and, in consequence, there is no vascular swelling of terminal bone marrow to cause pressure or growth from within, nor is there the likelihood of small neighboring nerve fibers being caught and held in the rough osseous proliferation which occurs when there is a periosteal covering for the end of the bone. Thus the painlessness of the stump after exarticulation, and after amputation through the epiphysis is explained as there is, in these situations, no swelling of the bone marrow nor does terminal osseous proliferation occur. The older surgeons, Pirogoff and Gritti, obtained excellent painless weight-bearing stumps by their well-known methods of utilizing a distal piece of bone attached to the covering flap and secured to the end of the bone in the stump, the former surgeon's method applicable to the ankle and the latter's to the knee amputation. As an application of this principle Sjabanejeff's idea of uniting the anterior surface of the head of the tibia with the lower end of the femur is an excellent one. Later on Bier amplified the same idea with reference to amputation through the diaphysis or shaft. His technique consists in securing an osteoplastic bone-covering flap, utilizing a part of the bone which is to be amputated though left attached to the covering flap. These various methods are excellent but their universal application is questioned by many surgeons who have in mind the character of the injury sustained and who hold that the simpler procedures are the best. Certain it is that in battle surgery or in case of a traumatic epidemic, such as railroad accidents, time will not admit of elaborate operations and we have recourse to the less pretentious methods of removing the injured part. In diaphyseal amputations these consist in mapping out ample flap covering, sawing off the bone cleanly with the removal of sharp edges or points, scooping out the terminal bone marrow, removing a small cuff of periosteum from the end of the bone, obliterating "dead spaces" and allowing for drainage. In epiphyseal amputations, or in exarticulations, there is no necessity for periosteum removal, or scooping out the marrow or any special covering.

Disturbances with the function of the stump, or its complete mobility as a perfect lever, are twofold. First of all the joint on which the stump hinges may become wholly or partially ankylosed if attention is not directed at an early stage towards manipulation of the lever. As soon as primary union has occurred the splint should be removed and the joint freely exercised passively so that adhesions will not occur to restrict the complete mobility of the joint. Secondly, disturbances with the lever action of the stump may be brought about by irregularity of muscular movement in the stump itself as the result of individual muscles, or groups of muscles, contracting irregularly and producing a distortion of movement. To overcome this condition the modern practice is *not* to pull the tendons out and cut them off as short as possible, as until recently was the custom, but to leave the tendons long and either to anchor them to the periosteal fascia or to unite the tendons of opposing muscles over the end of the bone, thus having flexors acting against extensors and preventing irregular contractures. This is especially applicable to amputations in the fingers, hand, and wrist where effort must be made to obtain good lever action in the stump. The same principle applies to groups of opposing muscles in stumps of the arm, forearm, leg, and thigh, either uniting antagonistic muscles or anchoring them close to the bone and in such a way that any future contractions of the muscles will not exert their action upon the covering of the end of the stump. Uniting opposing tendons or muscles over the end of the bone is the preferable procedure, as the anchoring of the muscle in close proximity to the skin flap has sometimes resulted in dangerous stretching of the skin covering the stump.

As already indicated, healing by first intention in amputations is of the greatest importance. This is not only on account of the infection being a highly undesirable and dangerous complication, although in many instances recovered from, but the resultant scar is broad and adherent, and is not only sensitive but liable to break down under the slightest pressure. In such circumstances the use of an artificial limb is practically out of the question unless excision of the scar, or reamputation, is resorted to. Even in primary union there may be a slightly adherent sinuous scar, the latter being due to irregular contraction of the skin, and it is now considered good practice to begin massaging and kneading the stump early, after primary union has occurred, shifting the parts against each other to insure complete mobility of the tissues and, in the lower extremity, a weight-bearing stump. As Binnie puts it, it is well to subject the end of the stump to a certain amount of therapeutic abuse, after primary union, with the idea of bringing about a quicker response in the tissues to the weight-bearing feature of the stump.

It remains to discuss certain special considera-

tions, in regard to amputations of the leg and forearm, which have in view enhancing the utility of the stump. In amputation of the leg the so-called "seat of election" for sawing the bones is one handbreadth below the top of the tibia or about one inch below the tubercle of the tibia. At this level the flaps are not only well nourished but the stump of the leg is long enough to support the weight of the patient on the bent knee without the end of the stump projecting too far behind. Not only is this a favorable site for the application of an artificial limb but the older surgeons recommended the "seat of election" for the reason that even a wooden peg with a padded shelf at the upper end, on which the patient kneels with his stump, makes a very useful and inexpensive artificial limb. However, this particular level for amputation is no longer regarded as essential in view of the modern methods of operating, and the improvement in artificial limbs, to secure weight-bearing, painless stumps.

Binnie, analyzing the statistics of Estes, thinks that as far as the mortality of amputations of the leg is to be considered there is practically no difference at which level the amputation is performed. The same author says that the makers of artificial limbs state that the lowest favorable site for section of the leg bones is eight inches above the ground and that the highest favorable point is four inches below the lower edge of the patella.

In deciding upon the level at which an amputation is to be performed Binnie brings out several important factors to be considered. In the first place, where the bones of the foot are affected by a malignant disease it is proper to amputate, by the best possible method, at any convenient part of the leg, while for the same disease of the tibia or fibula no amputation below the knee can be considered. With reference to gangrene, the level of amputation will largely depend on the extent of vascular disturbance and there are two methods given for determining the site of operation. Moscowicz's method is to elevate the limb for two or three minutes, apply an elastic constrictor to the thigh as if for amputation, and then lower the limb to a dependent position. After five minutes remove the constrictor rapidly. In health the arterial circulation is reestablished at once and a hyperemic flush passes down the limb to the toes in about two seconds. If gangrene is present the flush rapidly passes down the limb to a certain distance, then pauses so that there is a clear line of demarcation between the hyperemic skin above and the ischemic skin below, then the flush slowly passes downward, taking minutes instead of seconds to reach the toes. The line where the descending flush pauses corresponds to the site of arterial obliteration and the limit to which the gangrenous process may be expected to reach. Sandrock's method is much simpler and consists in scrubbing the leg vigorously as in preparing for operation. Note the reaction of the skin to the scrubbing. The well nourished skin becomes diffusely red and this flush stops more or less abruptly at the poorly nourished level. The amputation must be performed well above the Moscowicz-Sandrock line, and in elderly people with atheromatous vessels the amputation must be performed in the middle or lower third of the thigh in order to get proper flap nourishment. When the change is less abrupt, the transition zone shows either spotted or streaky redness. It is advisable to repeat the experiment on the healthy limb as a control. DaCosta lays down the following rules as regards amputation for gangrene: In dry gangrene due to obstruction of a nondiseased artery, wait for a line of demarcation. In senile gangrene, if it affects only one or two toes, let the dead parts be cast off spontaneously. If a greater area is involved, or the process spreads, amputate above the knee without waiting for the line. In ordinary moist gangrene, if there are not severe symptoms of sepsis, and if the gangrene is not rapidly progressive, wait for a line of demarcation, otherwise amputate high up. In traumatic spreading gangrene, and in many cases of diabetic gangrene, amputate high up. In ergot, carbolic acid, post-febrile, Reynaud's, and frost gangrene, wait for the line of demarcation.

When amputating for trauma the site of section depends on the site of injury and the amount of tissue which is left and which is suitable for forming the stump. The use which is to be made of the stump is a factor of prime importance in the choice of the site of amputation. If the financial condition of the patient is such that he cannot afford an expensive artificial limb it is of paramount importance to save as much of the limb as possible and provide him with a useful, painless stump which will bear the weight of the body, both continuously and intermittently, without harm resulting. Such an operation would be a Pirogoff or Syme at the ankle, a Gritti or Sjabanejeff or any of the many variants at the knee, and a Bier's osteoplastic anywhere between the two. In the case of amputations of the Pirogoff or Gritti variety, while they may not be approved of from the artificial limb maker's point of view who may want to sell an elaborate expensive limb, nevertheless they can be fitted with a strong, useful and not unsightly prothesis. In the same class of patients when the opportunity to carry out complicated procedures is lacking, the so-called "seat of election" is indicated for the reasons already given. If we can consistently secure an efficient weight-bearing stump at any level then it follows that for one who cannot afford an expensive artificial limb it is important to have no shortening of the leg; whereas in one whose social and financial condition is such as to warrant allowing the artificial limb makers to exercise their art, both as regards usefulness and cosmetic effect, then it would be better to follow their recommendations and section the bones eight inches above the ground or four inches below the lower edge of the patella when it is practical to do so. If disease and circumstance demand that amputation be performed at a level higher than the "seat of election" then it is advisable to disarticulate at the knee for the reason that the portion of the leg below the knee is not long enough to operate an artificial limb in such a manner as to preserve a normal or useful knee motion.

Binnie states that from his own experience it is not necessary to carry out Bier's elaborate osteoplastic amputation in regard to having a periosteal hinge for the bone flap, but that the same result can be obtained by a free transplant of bone for covering the cut end of the tibia, or long enough to also include the fibula. His modified technique is as follows: By any of the customary methods reflect the soft parts and expose the tibia, covered by its periosteum, for a few inches below the proposed line of bone section. Transversely divide the periosteum of the tibia along two lines, separated from each other by a space about one inch greater than the diameter of the bone. From the upper incision separate the periosteum downward for about two-fourths of an inch. From the lower incision

separate the periosteum upward for about two-fourths of an inch. Cut through the cortical bone of the tibia transversely at the base of the periosteal flap. With an osteotome or Gigli saw cut free the plate of bone between the transverse incisions. This plate of bone is covered by periosteum which hangs from its upper and lower edges like a table cloth. Preserve this in warm salt solution. Complete the amputation by sawing through the bones after forming a periosteal cuff on the tibia. Place the plate of bone over the cut surface of the tibia and fibula and fix there by periosteal sutures. As Binnie states, such an operation as the above is entirely out of place unless asepsis can be assured and the resisting power of the patient is satisfactory. In any amputation divide the soft parts by first cutting through the skin and fat down to the deep fascia, let the skin retract and then, cutting through the deep fascia, reflect it along with the skin. The muscles are now cut through obliquely upward and toward the bone, so as to make muscular flaps which will cover the bone evenly and themselves be smoothly covered by the fascia and the skin.

In amputations through the wrist joint, or through the lower third of the forearm, Vanghetti, after primary union, advocates a plastic operation on some of the tendons of both the flexor and extensor group of muscles. His idea is to form loops of tendons, covered by skin, one on the front and one on the back of the wrist. The artificial hand is so constructed that leather thongs secured to these loops of skin-covered tendons will enable the fingers of the hand to be closed when the muscles are made to contract. He claims to have gotten twelve pounds and more pull from these tendon loops. It seems to be well worthy of trial in selective cases and bids fair to improve the usefulness of the stump.

NEUROLOGICAL AND PSYCHIATRIC ASPECTS OF RAILWAY ACCIDENT CASES. CONSIDERATION OF SOME MEDICOLEGAL PROBLEMS.*

By ALFRED GORDON, M.D.,

PHILADELPHIA, PA.

The problem of railway accidents in its relation to nervous and mental disturbances has a considerable social importance. Among all the accidents those caused by railroads or trolleys give the largest contingent of victims.

The nervous system among other organs may suffer from the shock of the accident in two ways; there may be either a functional disorder or a genuine organic lesion. A neurosis, a psychoneurosis, or a veritable psychosis may develop subsequently to an accident.

The subject, as you see, is very great and too vast to allow of satisfactory discussion in the short time that you can spare. We will, therefore, consider briefly the organic disturbances caused by traumatism and then take up the functional disorders, called traumatic neuroses and psychoses, which are by far more frequent than the former.

A traumatism of the cranium may result either in a fracture of its individual bones especially at the base, in a concussion of the brain, or in a very brief and transient psychic symptom-group which rapidly disappears.

Fractures of the skull are frequently accompanied by a lesion of the membranes, brain tissue, and cranial nerves at the base. The blood-vessels, the sinuses, may also be torn, hence extra or intradural hematomata. If the arachnoid membrane is involved, the cerebrospinal fluid finds its way through the opening of the skull or through the nasal fossæ or through the external auditory meatus. Among all varieties of fractures of the skull the most frequent is the radiating one. The radiation toward the base is done by the shortest route. An injury to the frontal, occipital, or temporal regions of the skull will reach the anterior, posterior, and middle portions of the base respectively. In the latter form the ear and Fallopian canal are not infrequently involved. In fractures at the base the cranial nerves are invariably affected. The so-called fracture "par contrecoup" should always be borne in mind in considering injuries of the skull. There the lesion lies in another portion of the skull than in the one that was injured. In the cranial injuries with fractures there is usually no difficulty in recognizing the situation, as the symptoms are too conspicuous to be overlooked. The classical bleeding from the nose, mouth, or ears points to a fracture at the base of the skull. We usually find here palsies of various portions of the body and disturbances of sensations. The cerebral manifestations will depend upon the area of the brain involved. Disturbances of speech, epileptiform convulsions, and hemiplegia or monoplegia may all be present. It stands to reason that in all such cases the prognosis is of a serious nature on account not only of immediate but also of remote consequences.

Concussion of the brain is another important condition which may follow a cranial traumatism with or without fracture of the skull. The common belief that only in injuries accompanied by loss of consciousness there is concussion of the brain is erroneous. Records of authoritative cases show that even without loss of consciousness symptoms of grave nature may develop immediately or in a few hours or days after the accident.

In the majority of cases without gross injury of the brain, especially when there is no history of syphilis or alcoholism or fracture of the skull and when the treatment is instituted at the earliest possible moment, recovery is complete.

The usual manifestations of concussion are: pain in the head, dizziness, insomnia, mental hebetude, asthenic condition; later change of disposition, irritability. When recovery does not follow, grave mental phenomena may develop, such as impairment of memory, difficulty of retaining impressions, delirium associated with profound mental alterations, hallucinosis, Korsakoff's psychosis; finally dementia. In children arrest of mental development may ocur. Anatomopathological investigations show that in those severe cases in which various mental phenomena persist or become aggravated, actual material lesions exist. Sperling and Kronthal *(Neurolog. Centralblatt,* 1888, Nos. 11 and 12) found sclerosis, hyaline and fatty degeneration of the arterial system in the brain and cord. Dinkler *(Archiv f. Psych.,* Bd. 39, 1905) found the nervous tissue rarified, medullated fibers disappeared, gliomatous tissue proliferated, and blood vessels changed. Similar alterations were observed by Fürstner *(Zeitschr. f. Psych.* B. 38).

The subject of organic lesions of the nervous sys-

*Address delivered by invitation before the Surgeons' Association of the Norfolk and Western Railroad in Cincinnati, June 17, 1914.

tem caused by traumata will not be complete if mention is not made of the spinal cord. An injury of the cord may follow a trauma of the spinal column, such as fracture, dislocation, a blow, or a fall on the feet or on the buttocks. Under these circumstances there may be a concussion, a contusion, a sudden compression, laceration, or complete severance of the cord. In all these conditions there are usually present morbid symptoms of motor and sensory apparatuses, also disturbances of the sphincters. In concussion these symptoms may disappear completely, in the other conditions they usually become permanent. In all these cases a carefully conducted examination as to the state of the power of the limbs, sensations, reflexes, and sphincters will reveal the true nature of the condition.

Peripheral nerves may also become involved through a traumatism. An inflammatory state (neuritis) may follow a direct contusion or pressure of a nerve trunk. Hemorrhages may take place in a nerve and set up an inflammation. Motor, sensory, and trophic disturbances in the parts supplied by the inflamed nerve will be the consequence.

Let us consider now in detail the neuroses and psychoses which are of the most frequent occurrence and their immediate or remote relation to traumata.

The functional nervous diseases most frequently produced or brought out by railway accidents are hysteria and neurasthenia, or a combination of both. Chorea and paralysis agitans may also follow traumatism. A review of their clinical picture is necessary.

Hysteria.—This affection comprises two series of phenomena; one consists of *paroxysmal* manifestations which are not constant, and the other of *constant*, fixed, and permanent signs called hysterical stigmata of which the patient is not conscious and which can be elicited by a careful examination. The latter are the most signifiacnt. They are found in the motor, sensory, and mental spheres of the individual.

The *sensory* disturbances are the most important and the most striking. The most frequent form is *hemianesthesia.* It may vary in its intensity; at times it is increased, at others decreased. Sometimes it affects only one form of sensibility, viz., touch, pain, or temperature, sometimes two or all three forms. The loss of sensation may be present not only in the skin, but also in the underlying tissues, the bone included. The loss of sensation may be present only in the distant segments of the limbs (glove-like and stocking-like anesthesia). Hysterical patients present frequently hyperesthetic zones. They are along the spine, the mammary or ovarian regions.

Among the *motor* manifestations may be mentioned particularly palsies and contractures of segments of limbs. The well known astasia-abasia consists of an inability to stand or walk, but as soon as the patient is in bed he has full control of his limbs. The absence of abnormal reflexes, such as the toe phenomenon and ankle clonus, will aid to distinguish hysterical palsies from organic palsies. A very valuable diagnostic sign consists in the feeling by the observer of a resistance when he attempts to produce passive movements in the limbs affected with hysterical contractures. This tendency to resist on the part of the patient will not be present in organic paralysis or contractures.

The function of the viscera may also be disturbed in hysteria. Aphonia, mutism, anuria, polyuria, retention of urine, are all well-known phenomena.

The mental sphere of hysterical individuals presents special features. Temporary amnesia, capriciousness, inconsistencies, dissociation of personality may all occur. But the most characteristic feature is a high degree of *suggestibility.* Hysterical individuals are easily influenced to change their thoughts, to do certain acts, to acquire certain sensations, to execute or to adopt certain motor phenomena. For this reason the greatest care must be taken during the examination to avoid by word, look, or act, to remind the patient of what one expects to find in him. The proper and the only correct way of examining for sensations or other symptoms is to have his eyes closed during the entire procedure. According to the expression of his face during each touch or pin prick one can tell whether the sensation was perceived by him or not. In the section on medicolegal aspect of the subject mention will be made of simulation of hysterical manifestation. To sum up, hysterical stigmata are fixed phenomena which usually appear suddenly or rapidly under the influence of an emotion and may disappear quite rapidly, but never have any untoward effect on the general health. The effects of suggestion or autosuggestion on the appearance or disappearance of the stigmata will be discussed later.

Neurasthenia.—Its main features are physical and mental exhaustion upon the least effort and undue irritability. Backache, headache, insomnia, are frequently present. The symptoms are chiefly subjective. Among the objective manifestations may be mentioned emotionality, general hypotonia, increased tendon reflex, clammy skin, and the facies exhibiting anxiety.

Mental Phenomena Following Traumatism.—Among the latter *amnesia* deserves special mention. Loss of memory may be functional and organic. The characteristic feature of organic amnesia is its permanency and progressive course. In cases of traumata followed by organic lesions of the cerebral tissue the damage to the mnemonic faculty is dependent upon the brain lesion, and like the latter may remain permanent. When the trauma is not followed by a material intracranial lesion and is only functional in nature the loss of memory is due to the profound emotional shock caused by the trauma. The sudden commotion of the nervous system disturbs the mechanism of association of ideas with regard to time and place. Functional amnesia may concern only a certain group of ideas; it may be general, in which all past events are lost; it may be partial; it may be localized, concerning only a certain fact of life. We speak of retrograde amnesia when a certain period of time immediately preceding the trauma is forgotten. In anterograde amnesia the events immediately following the trauma are forgotten. These two forms may be combined.

Amnesia following an accident is, like the latter, sudden. In cases of loss of consciousness one observes that when the latter is regained the patient has no recollection of the accident. In the majority of cases traumatic amnesia is of short duration, especially if it is only of the retrograde or only of the anterograde type. The duration is more prolonged and persistent if the amnesia is simultaneously antero- and retrograde. The prognosis of traumatic amnesia is as a rule favorable. Exceptionally, permanent amnesia has been observed.

Korsakoff's Psychosis.—Sometimes subsequently

to cranial traumatism the following mental phenomena may be observed: As soon as the patient commences to speak he shows evidences of impaired memory and a tendency to fabrication with reference both to the accident itself and to recent events. Gradually these symptoms become accentuated. In the state of full development the following are the chief characteristics: Fabulation, false reminiscences, antero-retrograde amnesia, illusions of identity. The injured individual creates the most fantastic account of his accident and other events. He mistakes his surroundings, relatives, and friends, but he is able to recognize those with whom he always lived, such as wife and children. However, his judgment, reasoning, and emotivity are intact. Very occasionally hallucinations are met with. Ordinarily recovery is complete, but it is slow; the disease lasts several weeks or months. Exceptionally the affection becomes protracted, especially when an asthenic state is present, and it may remain permanent when enfeeblement of the mental faculties develops.

Confusion.—A state of mental confusion may follow immediately, a few days later, or a considerably longer time after a trauma. In the first case as soon as the victim of the accident regains consciousness and sometimes without loss of consciousness he finds himself disoriented like individuals recovering from the effect of an anesthetic. The most frequent occurrence is when a confusional state develops a few days after the trauma, such as we observe in postpuerperal or postoperative cases. In still another group of cases the confusion occurs several weeks or months later. Here it is probably due to nutritional disturbances, to prolonged confinement to bed, etc. The characteristic features of the disorder are mental obtusion, amnesia, disturbed perception, non-recognition of surroundings, illusions of identity, impaired emotivity, incoherence, and disorientation; hallucinations and delirium may supervene. The outlook is usually favorable, except in cases of visceral complications and in delayed cases. The rapidity of recovery varies with the intensity of the disorder and with the date of its appearance, viz., the earlier it is the more favorable is it.

Dementia.—In the chapter on concussion mention was made of the fact that in cases which do not recover anatomical lesions are present in the central nervous system. While these lesions may be exceedingly slight and may heal, nevertheless sometimes they are the point of departure of new and extensive degenerations producing eventually profound intellectual deterioration, viz., dementia. Thus under the term *traumatic dementia* should be understood a chronic and progressive enfeeblement of mental faculties which is associated with circumscribed or multiple lesions of the cerebrum following a cranial traumatism. The terminal deterioration of mental faculties usually follows a course of various psychic disturbances. Immediately after the trauma there may be a period of a confusional or delirious state or amnesia. On the other hand, these symptoms may be absent and the evolution toward dementia may be very slow. In such cases the following symptoms are manifest: Headache, which is usually constant, vertigo, somnolence, asthenia, changes of disposition and of character, great impressionability, emotivity. Gradually diminution of mental power becomes noticeable. Amnesia is the first to become conspicuous. Power of attention suffers subsequently. Inability to continue the usual occupation becomes evident. Judgment commences to fail. The patient becomes apathetic, depressed, indolent; his mental faculties undergo more and more profound alterations.

A distinction should be made between post-traumatic dementia and *paretic dementia.* The relation of paresis to trauma is a question of great importance. For a long time a few alienists of note believed that an injury is apt to develop paresis. In the light of our present knowledge, concerning especially the complement fixation test, it may be safely said that paresis is not and cannot be caused by an accident. We are now in possession of biochemical means to determine the nature of paresis. The positive Wassermann reaction of blood-serum and cerebrospinal fluid, increase of albumin in the latter, lymphocytosis are all pathognomonic of paresis. Besides, spirochetes have been found in paretic brains. There is only one cause of paresis, viz., syphilis. If the symptoms of paresis become sometimes conspicuous after a trauma it is because the disease existed before the accident and the latter served only as an exciting cause for its more rapid development.

Paresis will be differentiated from post-traumatic dementia also by means of a number of physical signs which are so characteristic in well-developed cases that an error is difficult. They are: irregular and unequal pupils, fine tremor of hands, tongue, and lips, typical speech.

Epilepsy in Relation to Trauma.—In a fracture of the skull a fragment may press directly on the cortical layer of the motor area and produce convulsions. In other cases there may be some cicatricial tissue with thickening of the meninges, producing an irritation of the motor area and therefore convulsions. In all such cases the trauma is the original cause of epilepsy. But there are cases in which no appreciable lesion of the motor cortex had been found and still epilepsy developed after a trauma. In every case of this nature one must bear in mind the possibility of pre-existing epilepsy or of a special predisposition to it through alcoholism or syphilis. Here the trauma plays the rôle of a contributory factor. With our present methods of investigation this question can be easily settled. The Wassermann test, the Noguchi test, and their modifications will enable us to determine whether a given individual is syphilitic or not. In all such cases a careful search should be made into the personal and family antecedents before the relation between the trauma and epilepsy is reasonably established.

Medicolegal Considerations.—When an expert is called upon to express an opinion regarding disturbances of a nervous or psychic order following a trauma he is confronted with the following problems: (1) What exactly is the disorder produced? (2) Is the disorder genuine or simulated? (3) Should the symptoms observed be attributed to the traumatism? (4) If the latter is correct, what is the degree of incapacity for work: complete, incomplete, temporary, or permanent? (5) What are the prognosis, duration, and termination of the malady?

1. As to the first question, the description given in the foregoing pages of various nervous and psychic disorders must always be borne in mind.

2. The determination of simulation is, as a rule, not difficult. Nevertheless, in some cases great embarrassment may be experienced. When the symp-

toms are objective, they will be easily recognized. It is absolutely impossible for anyone to simulate an anesthetic pharynx, an anesthetic conjunctiva, a contraction of the visual fields, a genuine hemianesthesia, a genuine plus reflex. These symptoms which are characteristic of hysteria, cannot be confounded with any other nervous affection. It is true that an hysterical paroxysm with its screaming, laughing, and various motor and psychic phenomena can be to a certain extent simulated, but an experienced physician familiar with the disease will have no difficulty in recognizing it. The psychic symptoms of hysteria are not ordinary symptoms; they present a special physiognomy, the main points of which can never be guessed by the simulator. It is the entire picture of the attack that should be taken into consideration, not individual elements.

Special attention is called here to the most important feature of hysteria, which if overlooked will lead to errors of diagnosis and consequently to unfairness in the expert opinion; justice may, therefore, suffer. In the section on "Hysteria" mention was made of the element of suggestibility in hysterical patients. Anesthesia of segments of limbs or of whole limbs, contractures, palsies may all be suggested by friends or the examining physician. The examination, therefore, must be conducted with extreme care. It should be the rule to conduct the examination with the patient blindfolded. No question should be asked of him while the test for sensations, for example, is being made with a pin over various areas of the skin. There is no doubt that he will make some defense movement if the prick causes pain. Or else the patient may be asked to say "yes" the moment he feels pain or the touch of an object. No mention should be made to the patient of possibilities of loss of power in one or more limbs or segment of a limb, of loss of memory, of a grave outlook, etc. Various disturbances of function in the motor, sensory, vasomotor, vegetative, and psychic spheres may be suggested to an hysterical patient with great facility. It is a common experience that not infrequently the victim of an accident immediately after the latter occurred and before he actually recovered from the traumatic shock, is surrounded by a multitude of persons, professional men as well as men otherwise interested. From that time on the individual never ceases to be reminded of his alleged injuries, whether they are genuine or not, until the time of the trial in court has arrived. Should this individual be somewhat neurotic, he at once commences to believe, honestly enough, in the existence of a real diseased condition. Suggestion and autosuggestion do the work. Hysterical stigmata may thus be induced and the man becomes then a victim of an induced or cultivated functional nervous affection which may follow him through his entire life. The guilty party is then not the railway employees but the professional men whose professional attainments were wrongly used. The involuntary negligence of the railroad in such cases is considerably less harmful to the victims of the accident than the voluntary and conscious misuse of the mental power of some interested or friendly persons foreign to the railroad.

Hysterical individuals possess a special mentality, viz., that of dependence and of servility. By virtue of these faculties they succeed in adapting themselves to any given circumstances through all sorts of means—ruse, fraud, simulation. They are capable of lying, of crying when necessary, of complaining of all kinds of suffering. They are capable of concealing their real feelings, of shamming those which they do not possess but which may be advantageous, of using subterfuges with the object to arouse sympathy and interest. Eventually they acquire a certain skill in these performances which they accomplish without any effort. They commence then to experience pleasure in such exercises and by virtue of repetition they become totally identified with them. Thus simulation, suggestibility, and autosuggestion are the chief characteristic features of hysteria.

In spite of the frequency of suggested hysterical manifestations, brought on unconsciously or consciously in railway traumata, there are, nevertheless, genuine occurrences in which hysteria could be considered as the direct result of the trauma. We must admit that the emotional element created by the shock of the trauma is capable of producing functional nervous disorders. There are unquestionably genuine cases with genuine unsimulated morbid manifestations which every fair-minded neurologist must admit. The plea is merely made here for a fair discrimination between what belongs to the emotion caused exclusively by trauma and the facility with which a functional nervous disorder may be induced by extraneous elements.

If simulation and suggestibility play an important rôle in the diagnosis of hysteria, inasmuch as the true situation before a court of justice seems at times most obscure, in the other functional nervous disorder, *neurasthenia*, the medicolegal problem is almost invariably surrounded with difficulties. In hysteria, as we have seen, the symptoms are chiefly objective; they are evident and demonstrable. In neurasthenia they are largely subjective, and therein lies the legal difficulty. When a victim of an accident complains of backache, fatigue, insomnia, and irritability there are no means of vertifying the presence or absence of each of these symptoms. Particularly when the latter are mild the difficulty is great. In such cases simulation has a fertile soil and the patient's exaggeration of his aches and pains has extensive possibilities. When the disease is pronounced, the general aspect of the individual will aid in forming an opinion as to the veracity of his complaints. There is usually loss in strength, pallor of the face, depression, cold, and clammy skin, tremor. In all cases, however, the expert in forming his opinion should not lose sight of the fact that the patient may be a sufferer after all and a judicious consideration should be given to his complaints. In justice to both parties he is duly bound to weigh carefully all the facts of a given case irrespective of the side he represents. Experience, judicious mind, sense of fairness are his guides.

The other functional nervous disease occurring after a trauma are chorea and paralysis agitans. Here simulation is impossible; but whether these maladies are in direct relation to trauma is to be determined after a most searching scrutiny. Care should be taken to ascertain whether the victim of the accident did not present prior to the accident some of the movements or some of the tremor of chorea or paralysis agitans respectively. In the majority of cases this will be found to be correct. It is rare that a trauma is the direct cause of these affections, although it is not impossible. In the latter case there will be found a susceptibility and a special predisposition in the individual's make-up to disorders of the nervous system.

Medicolegal Aspect of Amnesia.—Here great difficulties may be encountered. Simulation is relatively easy. Prejudicial judgment is a common occurrence. In cases both of transitory and of prolonged traumatic amnesia, extraordinary care, skill, and tact must be displayed in interrogating the victim of the accident; all circumstances surrounding him at the time of the accident must be taken into consideration before a final unbiased opinion is expressed. It is well to bear in mind that in the majority of cases the prognosis is favorable.

In Korsakoff's syndrome following a trauma reservation should be made in cases accompanied by asthenia and in cases with distinct enfeeblement of mental faculties. Ordinarily recovery is complete. The medicolegal opinion should be based therefore on the above considerations.

Confusional insanity bears usually a favorable prognosis and recovery in ordinary cases is prompt. From a medicolegal standpoint a final opinion should be reserved and the victim be kept under prolonged observation, as complications alter the outlook, although the complications as a rule are not dependent upon the confusional state itself.

In traumatic dementia trauma plays a conspicuous rôle from a medicolegal standpoint. Here the dementia is identical with the enfeeblement of intellect observed in cases with cerebral lesions of other origin, such as vascular, syphilitic, alcoholic, saturnine, or arteriosclerotic. Traumatic dementia is an organic dementia and consequently chronic, progressive, and incurable. It should also be borne in mind that remissions, *i.e.* periods of mental improvement, are possible and they may last a more or less prolonged period of time. The medicolegal aspect is here evident. The relation of the trauma to the mental condition is direct and the victim is entitled to damages. But if trauma occurs in an aged, arteriosclerotic, or alcoholic individual, the rôle of trauma is considerably diminished. It is no more a determining, but an exciting or accessory cause. Finally should dementia develop several years after the trauma without intermediary morbid phenomena the above mentioned causative relation of the trauma cannot be taken into consideration from a medicolegal standpoint.

The question of *paresis* can be dismissed in a few words. In the light of our present knowledge there can be but one cause of paresis, viz., syphilis. As to the medicolegal rôle of trauma, the following considerations, I believe, are sufficient to establish its relationship to paresis: (1) Traumatism is not a direct cause of paresis. (2) If symptoms of paresis appear immediately after a trauma, the latter is only an accessory or aggravating cause of the disease which had already existed before the accident. (3) When paretic symptoms appear a long time, say years, after the accident, there is no relationship between the two. Freedom from symptoms referable to the old accident should be considered as a recovery.

The medicolegal relation of *epilepsy* to trauma can be considered only when the convulsions which never existed before the accident, make their appearance immediately after the latter. Late epilepsy may be considered as being the result of an old trauma only when during the intermediate period various symptoms, such as vertigo and headache, persist with great obstinacy.

The next problem which we outlined in the beginning of this chapter is the determination of the degree of *incapacity* caused by the accident, the consequences, duration, and termination of the latter. Hysteria and neurasthenia are not synonymous of simple nervousness. Properly understood they are well-defined diseases of the nervous system. They do incapacitate for mental or physical work, but only to a certain extent. The anesthesias, hyperesthesias, contraction of visual fields are well borne by hysterical individuals, but the psychic phenomena of hysteria, such as great emotionality, irritability, restlessness, crying spells, paroxysmal attacks, are all apt to produce disability, mental as well as physical. The mentality of hysterical individuals is peculiar. Lack of concentration and application, incomplete association of ideas because of instability, want of deep mental processes; great impressionability and unusual responsiveness—are all manifestations which render an hysterical individual unfit for mental or physical work. It stands to reason that hysterical contractures or palsies are also elements unfavorable for resumption of the individual's former or any other occupation.

In neurathenia the physical and mental fatigue upon the least exertion, the backache and headache, etc., are all phenomena which incapacitate the victim of an accident for work.

In determining the degree of incapacity in these two affections the ever present possibility of simulation and the powerful influence of suggestion should never be forgotten. It is, therefore, evident that a very careful inquiry into the victim's entire social and medical histories must be undertaken. His complaints must be thoroughly scrutinized. The opinion on partial and total disability will depend upon such an investigation as well as upon the intensity of each individual symptom.

When amnesia occurs, a disability will ensue if it is of a generalized character. If it concerns only a certain past period of life (retrograde or anterograde form) there is no disability whatever. The individual is perfectly able to earn a living, as the memory is good for all events except that one.

The question of incapacity in psychoses can be settled in the affirmative by virtue of the mental disorder. The duration of the former depends upon the duration of the latter (see the respective sections).

Traumatic epilepsy does not remove entirely the capacity for work but frequently it becomes complicated by nervous and psychic disturbances. In the latter case it may lead to dementia. The outlook is naturally uncertain. The sudden and unexpected manner with which an epileptic seizure makes its appearance is a sufficiently strong argument in favor of incapacity for physical work. As epilepsy is of uncertain duration, the claim for compensation should be considered accordingly.

The previous study of trauma in relation to nervous and mental disorders leads to the following conclusion: In cases of railway or other injuries caused by neglect of those who have in charge the management of transportation, it is no more than just that the injured person should be compensated for disability. On the other hand, simulation or exaggeration of incapacity should be condemned. The physician is indispensable to the law. In the name of justice he must be invariably reserved in his statements. His opinion must be formed after a thorough study of each individual case. The degree of the disability and the prognosis of the affection vary in each individual case. The scientific recognition of the affection, the recognition of the influence of the accident upon its mani-

festations, finally the discrimination of a genuine malady from a simulated one—all these elements can be acquired only when the physician is properly prepared.

1812 Spruce Street.

THE MODERN TREATMENT OF SYPHILIS.

By W. H. WATTERS, M.D.,

Boston, Mass.

Pathologist, Massachusetts Homeopathic Hospital.

The question of syphilis and its treatment has always been a very important one in the practice of almost every physician. Apart from its sociological aspects, however, it is one that has been largely banned in scientific medical assemblies. This has been on account of the actual very vague knowledge concerning its cause, its accurate diagnosis, and its proper treatment.

During the past few years, however, the exciting cause has been discovered, an accurate method of diagnosis has been worked out, and a very efficient therapy has been introduced. The result is that patients suffering from the disease are now admitted into practically all of our general hospitals and there efficiently treated. In other words, the disease has been elevated from its lowly station where mercury and the iodides were prescribed in a hit or miss manner to a higher plane where its progress can be accurately watched by exact laboratory methods and the efficiency or further need of various forms of treatment can be definitely determined. In short, syphilis can now take its proper place in scientific medicine.

The present is not the place to take up the topic of the discovery of the *Treponema pallidum* by Schaudinn. Neither can prolonged attention be given to the important phenomenon best worked out by Wassermann and named after him the Wassermann reaction. Before going further, however, a pause must be made to state that it is incomprehensible how a physician can properly treat a case of syphilis at the present day without repeated blood and in many instances spinal fluid examinations. Without such, many cases, apparently cured, will recur, and in other instances the correct diagnosis will be entirely overlooked.

The Wassermann reaction must rank as of primary importance in the treatment of the disease, but it has its limitations. It must be borne in mind that it is not an absolutely specific complement fixation test as is that used in gonococcus infection. It must be also remembered that it is not present in the early primary stage, and not always in the tertiary or quiescent ones.

When properly performed and interpreted it will prove to be an invaluable guide and one that cannot safely be dispensed with. It should always go hand in hand with treatment. With this preliminary, the main topic of this paper may be introduced, viz., the treatment of syphilis. As has already been stated, until very recently there were two remedial agents, mercury and potassium iodide. A patient received sometimes one, sometimes the other, sometimes mercury by mouth, sometimes by inunction, or again by subcutaneous, intramuscular, or intravenous injection. If he showed signs of improvement well and good. If not, there was practically nothing further to try, and only too often he fell into the hands of charlatans. Thanks to Ehrlich, a remedy is now available that will compare in efficiency with quinine in malaria.

Time and your patience forbid description of the various steps in the study of the spirillicidal forms of arsenic from the simple drug through the more complex forms such as atoxyl to salvarsan and its younger cousin neosalvarsan. It must be sufficient to state that in these new drugs there was supposed to have been discovered that ideal of the bacterial therapeutist, substances sufficiently potent to kill the specific parasites without injuriously affecting the host. When first brought forward it was supposed that one treatment of salvarsan would efficiently rid the host of all its treponema parasites. And indeed, in some instances, the clinical improvement was so startling after one such treatment as almost to justify that belief. It was very soon found to be fallacious, however. Again in the early administrations, various severe forms of reactions were sometimes noted. Accordingly further research was instituted, with the result that shortly a new product, neosalvarsan, appeared. This was supposed to be more potent and to give rise to less reaction. Whether this is true is still somewhat debatable.

Perhaps the most logical manner to take up the further presentation of this subject is to give in some detail the routine followed in treating various stages of the disease, the prognosis, and precautions involved. It may be well to state that these opinions are based practically exclusively upon personal experience after administering the treatment a large number of times and always controlled by careful Wassermann tests.

Primary Syphilis.—Search for *Treponema pallidum* in chancre. Take blood for Wassermann reaction. Remember that this reaction, like the Widal reaction in typhoid, may not appear for days or even two or three weeks after the onset of the disease. A negative reaction thus early will not accordingly exclude the possibility of syphilis. Repeat in a few days. When satisfied concerning the diagnosis, the earlier the treatment is begun the better the hope of recovery. Instruct patient to empty bowels by cathartic and to eat nothing for several hours prior to treatment in order to have empty stomach. Introduce into median cephalic or basilic vein (or some other) 0.4 gram salvarsan while patient is lying down. Preferable time, late afternoon. Least reaction comes when patient remains quiet in bed till morning, although often it is comparatively safe to allow one to go home and then to bed. Eat nothing for several hours after, and no solid food till next day. Water as desired. Then live as usual after twelve hours.

Possible reactions: nausea, vomiting, headache, chills, diarrhea, fever, occurring within twelve hours. Varying reactions in possibly 10-20 per cent. of cases, less when salvarsan is diluted with 50 per cent. saline freshly made from freshly distilled water. Never allow mixture to stand more than fifteen to thirty minutes, and never mix up enough for two patients at same time. Repeat above process in seven and again in fourteen days, increasing the dose to 0.5 gram and 0.6 gram respectively. During this time administer mercury protiodide, at first 2x homeopathic trituration and later 1x to limit of toleration (indicated by cramps in abdomen, diarrhea, salivation, sore mouth, etc.). Follow by salicylate of mercury in sterile olive oil (50 grains mercury to 1 ounce olive oil, warmed and mixed before use) intramuscular (buttocks), once a week in doses of ¼ to 1 grain. Continue for three months. Discontinue all medication for three weeks and then do a Wassermann. If this

is negative, or feebly positive (+) continue mercury for three months more. If positive, repeat the salvarsan treatments, and the following mercurialization. Each case should be watched for at least one year, and preferably two, even if the Wassermann becomes negative early, as it sometimes changes back to positive. The first salvarsan treatment will probably strongly affect the chancre, causing it to dry up rapidly and subside. Local treatment is seldom necessary. The enlarged lymphnodes may be more obstinate. All clinical symptoms will usually clear up promptly, and the patient will feel perfectly well. From the standpoint of prognosis, the person can be told that the symptoms are almost certain to subside promptly, and that there is a fair chance of complete recovery as indicated by repeated and continued negative Wassermanns. Remember that mercury recently taken in quantity, also alcohol, may make an otherwise positive reaction negative. Strongly conclusive evidence that it is possible definitely to cure a syphilitic patient has been brought forward in a number of instances where a person has for the second time had a typical chancre following a second exposure with all symptoms of a fresh attack, a phenomenon impossible were any of the old infection left in the body. This is something practically unknown in the presalvarsan period.

Secondary Syphilis.—In this stage the Wassermann reaction is practically always present. It is here of the greatest definite value as a negative reaction, especially if repeated, on a suspicious dermatitis, pharyngitis, etc., is strong presumptive evidence against the existence of the disease. Here search can be made for the specific organisms in the lymph from the various local lesions. The course of treatment to be followed is identical with that already outlined. By it one may confidently expect to eradicate promptly the local and general manifestations of infection and to give soon to the individual a goodly share of health and wellbeing. Careful observation for one or two years is essential to the proper disposition of the case, if for no other reason than as a means of insurance against future outcropping of some of the late protean manifestations.

Under conditions as above detailed there is reason to be quite hopeful for a complete and permanent cure. It may entail many salvarsan treatments, much prolonged mercurialization, and repeated blood examination. Even if it proves impossible to obtain a permanently negative Wassermann reaction, further trouble can be quite definitely prevented.

Tertiary Syphilis.—This stage of the disease can take almost any form, and is manifold in its manifestations. The Wassermann reaction is here more variable than in the two preceding stages, it being absent in from 15 to 30 per cent. of all cases, particularly those of the latent or dormant type. A positive test is always significant. A negative one is much less so. In the presence of suggestive history or symptoms it should always be repeated several times, and if it is in any way associated with the central nervous system, lumbar puncture should be performed and examination made of the cerebrospinal fluid. Frequently cerebrospinal syphilis will not manifest itself at all in the blood, while doing so very clearly in the spinal fluid. In these or other forms of the disease with negative Wassermanns one or more so-called "provocative" salvarsan treatments will clear up the case readily. The luetin skin test, as introduced by Noguchi, is also often of value in elucidating otherwise obscure cases. With the diagnosis definitely settled the particular type of treatment should be considered. In all cases not connected with the central nervous system the course of treatment already outlined should be carefully followed and continuous observation is essential, either indefinitely or until such a time as there shall have been Wassermann negative blood tests over a period of months. As in the primary and secondary stages, so here, the various clinical manifestations will clear up with readiness and a feeling of general wellbeing will replace the less agreeable ones. The hope of obtaining entirely negative serological tests is less than in the earlier stages. That the patient can be greatly improved and the majority of the symptoms entirely eradicated may be strongly anticipated, however. Such cases require prolonged and often indefinite observation in order to guard against return of the symptoms or appearance of new and more serious ones.

Syphilitic Nervous Diseases.—When the disease has become located in the central nervous system, and the treponemata have become lodged in tissue poorly supplied with circulating blood, it is very difficult to attack them successfully by the usual intravenous administration of salvarsan. It has been definitely proven that very little salvarsan thus administered ever reaches the nerve tissue involved, and accordingly the therapeutic results are discouraging. In order to obviate this difficulty Swift, working in the Rockefeller Institute, has advised the introduction directly into the spinal canal of fresh but inactivated blood serum obtained from the patient one hour after a salvarsan treatment. This serum contains the drug in a form innocuous to the nerve tissues, but still distinctly lethal to the treponema with which it can by this means be brought into direct contact. The method is a complicated one, and practicable only in an institution accessible to a properly equipped laboratory. The method of choice to follow in syphilitic nervous disease should be in most cases the preliminary intravenous administration of salvarsan, repeated two or three times and controlled by serological study of the blood and the cerebrospinal fluid. If the results are not sufficiently evident, then the intraspinous injection of salvarsanized serum should be employed.

In tabes and general paresis experience has shown the vastly greater improvement following the latter treatment than that from the intravenous method. In these diseases, accordingly, it is inadvisable to waste time in preliminary experimentation when it is known how much more definite results can be obtained from the intraspinous treatment. It insures all the beneficial results of the intravenous plus those of the intraspinous as well. Where facilities for the latter are lacking, the former should of course be employed.

Did time permit cases might be cited where the girdle pains of tabes, and many other symptoms but little if at all ameliorated by intravenous treatment, disappeared most promptly after the intraspinous with corresponding general improvement.

In tabes and in paresis it is necessary to continue the treatment much longer than in the less severe forms of the disease. Intraspinous treatment is advised at intervals of about two weeks, and is repeated six, ten, twelve, or more times. In tabes with positive Wassermann in blood, or spinal fluid, or both, the outlook for benefit is good if the treat-

ment is persistently carried out. Time has not yet sufficiently elapsed to justify definite statements concerning the possibility of absolute cure. In paresis there is divergence of opinion on the part of various workers. In the cases upon which this paper is based, sufficiently encouraging results have been obtained to justify a continuation of the treatment and particularly persistence in its application. Certain conclusions have been reached as a result of the personal study here involved.

1. Salvarsan is preferable to neosalvarsan from both the clinical and the serological standpoint. When properly prepared, the reactions are not materially more numerous or more severe.

2. Salvarsan alone is less efficient than when accompanied and followed by mercury, preferably in the form of the salicylate intramuscularly.

3. Treatment should always be controlled by repeated blood examinations. It is accordingly best administered by one in close touch with a well-equipped laboratory.

4. In view of our present knowledge, treatment of any form of this disease has been inadequate when salvarsan has not been employed.

5. In tabes, and possibly in paresis, a practically hopeless disease has been transformed into one where much benefit can be confidently anticipated. Here the intraspinous route is the one of choice; this treatment should be administered only by one specially trained in laboratory technique.

6. Syphilis has been transformed into a disease capable of being accurately watched and efficiently treated.

ACUTE LEUCEMIA.

By AUGUST STRAUCH, M.D.,

CHICAGO, ILL.

It is well known that the blood pictures of acute lymphatic leucemia in the majority of cases are leucemic from the beginning throughout the course; but occasionally they may be subleucemic or aleucemic and even leucopenic for a part or all of the time, as clinical observations in connection with post-mortem findings prove. (Cases of Jeanselme, of Weil with 4,000 white cells, and of Benjamin-Sluka with 2,500 per cubic millimeters.) The cases of Hand, Potpeschnig, Churchill, Dosmarus, Naegeli (quoted from Benjamin), and a number of other cases presented more or less normal numbers of leucocytes; partly due to the effect of *x*-rays or infections, but partly these cases had throughout their course aleucemic or subleucemic blood pictures.

The degree of leucocytosis in the beginning of the disease may be insignificant or absent; even leucopenic pictures are to be observed, as, for instance, in the sixth case of Betz with 1,900-2,500, and later with 101,100 white cells. As a rule a rapid increase in the number of the leucocytes takes place; occasionally up to several hundreds of thousands of white corpuscles per cubic millimeter, though generally only moderate figures are met with in the acute form of leucemia. The quantitative changes of the blood pictures may be strikingly rapid; sometimes not until the agonal stage do the leucemic blood changes make their appearance, as for instance in the observation of Naegeli, where 7,500 leucocytes with 30 per cent. lymphocytes were counted the day before death, and 50,000 post-mortem.

Secondary infections as pneumonia, otitis media suppurativa, erysipelas, and especially septic complications may cause not only a subsidence of the clinical symptoms as far as the size of the lymph glands, spleen, and liver is concerned, but also a decrease of the leucocytosis to even subnormal figures, without of course improving the unfavorable prognosis. Should the lymphatic blood pictures not be well marked and at the same time the neutrophile polymorphonuclear cells be numerically increased, a diagnosis of acute leucemia may at this time be impossible. It is evident that such cases running temporarily or permanently aleucemic courses in the presence of more swollen lymph glands may be taken for "pseudoleucemia" in the wider sense, on which point I shall dwell later.

On the other hand acute lymphomatoses are observed that corresponding histologically with leucemia have clinically neither swellings of spleen nor lymph glands, and run their course under the picture of hemorrhagic diathesis or severe anemia. For the recognition of such cases and of the acute lymphemias with only a slight increase of the total count of the white corpuscles the qualitative blood findings may exceptionally fail. In the majority of cases there is fortunately a numerical prevalence of the lymphocytes, especially of the large forms, so that with a subnormal or normal total count of the white cells the percentage of the lymphocytes may reach 90 or more. However, in the last years cases, as mentioned, have been repeatedly observed (Hirschfeld) where even the relative increase of the lymphocytes was absent, although pseudoleucemia (Cohnheim's) was revealed by post-mortem. Subleucemic conditions may cause further difficulties in the diagnosis, because high absolute lymphocytoses occur also in typhoid fever, a relative lymphocytosis is to be found normally in infants and also in congenital lues and in pernicious anemia; also wound sepsis, widespread streptococcic adenitis of tonsillary origin may be accompanied by a lymphocytosis so pronounced as to suggest leucemia. No cause is known for this substitution of lymphocytosis for the usual polymorphonuclear leucocytosis of infections. The recognition of an infectious origin for the adenitis, perhaps a lesser degree of lymphocytosis in the infectious type and the course of the disease would determine the differential diagnosis. Here also may be mentioned such cases as observed by Türk (staphylococcus sepsis, with the picture of angina lacunaris and the blood finding of acute subhymphemic lymphomatosis) or Benjamin (two children with exudative diathesis showing for months 80 to 85 per cent. lymphocytes without true leucemia) and Ewald (leucemia without leucemic blood).

Atypical conditions of the blood pictures in leucemia must be considered as the expression of functional and biological differences in the leucocytopoesis and as related to one another; this relationship seems also to exist between the microlymphatic and macrolymphatic forms, inasmuch as these two forms may replace one another during the course of the disease, especially the latter the former; or both cells are present in the same case in a greater number but in various proportions. As a rule the prevalence of the larger "lymphocytes" and Rieger-forms indicate a more malignant and rather acute course of the disease.

According to our present views there exist no essential differences between leucemia and aleucemia (aleucemic lymphomatosis) or pseudoleucemia in the stricter sense (Cohnheim's). Several authors would abolish entirely the term "pseudoleucemia" since it comprises various pathological entities. As

"white-bloodedness" (Weissblütigkeit) can no more be considered as the essential factor in the leucemic processes the proposal of Ellermann and Bang to replace the term leucemia by "leucose" deserves consideration.

Türk introduced the term lymphomatosis for all diseases characterized by a pathological proliferation of the lymphoid tissues; he distinguishes alymphemic, sublymphemic, and lymphemic lymphomatoses according to the blood findings. In Orth's book on special pathological anatomy the term "pseudoleucemia" is altogether omitted. Identical anatomical changes are present in both diseases; though it is unknown, why in the one case the blood is overloaded with leucocytes, in the other not. The idea of the essential identity of the nature of leucemia and aleucemia is supported by the observation that during the course of typical leucemia periods of pronouncedly leucemic and aleucemic blood pictures may follow one the other and that an aleucemic or sublymphemic lymphomatosis may turn into a genuine lymphadenoid leucemia. Also the results of experiments by Ellermann and Bang on animals confirmed by Hirschfeld and Jakobi speak in favor of an etiological identity or similarity of the processes. The first mentioned two authors inoculated chickens with an emulsion of the organs from a leucemic chicken and produced in some of the animals leucemia; in a number of those animals, where the blood pictures failed to become leucemic, the hematopoetic organs, however, presented leucemic changes; chickens infected with aleucemic material presented severe leucemic blood pictures. In addition to that only recently Ellermann and Bang using one and the same leucemic material succeeded again in producing in chickens experimentally both the lymphatic as well as the myeloid forms of leucemia with corresponding anatomical histological lesions, similar to those in lymphatic and myeloid leucemia in man. In one of the chickens there developed "pseudoleucemia." Some animals inoculated with material filtered through porcelain filters showed pictures of leucemia, others of "pseudoleucemia." One chicken presented the picture of leucanemia.

These experiments tend to demonstrate the etiological identity or relationship of myeloid and lymphatic leucemia and aleucemia, and prove that the virus of chicken leucemia, which latter anatomically and hematologically corresponds with human leucemia, is filterable. Though these observations deal only with chicken leucemia, they are at least very suggestive as to the possibility that also the human leucemia is identical with aleucemia (pseudoleucemia in the stricter sense). Von Wiczkowsky succeeded in transmitting leucemia from man upon chicken.

The majority of authorities have long been inclined to refer the cause of acute leucemia to infection; some consider the disease as an infection with staphylococci or streptococci accompanied by a peculiar, abnormal reaction of the bone marrow, due to a constitutional inferiority; among the new authors (Paltauf, Neusser, Herz) the possible connection with status thymicolymphaticus has been repeatedly pointed out. Proescher on the other hand found spirochete in the fluid obtained from the lymph nodes.

The following case is interesting on account of the gradual decrease of the number of the leucocytes to a marked leucopenia.

Miss Mary G., of South Haven, Mich., was sent to Chicago by her physicians with the diagnosis of acute leucemia. Admitted to the Presbyterian Hospital on September 27, 1913. She had as child, measles, chickenpox and mumps, but was otherwise always healthy; in June she felt well and was able to walk several miles daily to and from school. The present illness began about four to five weeks ago, when she began to be easily tired on exertion, and suffered from severe diarrhea with 5 to 7 liquid stools a day, accompanied by abdominal pain, and lasting for about a week. At this time she was pale. About three weeks ago patient began to be short of breath on climbing stairs and to require more sleep than before. Often vertigo and nausea. The last menstruation anteponed by about one week with the usual loss of blood. Patient became gradually weaker and is, since a week, bedfast on account of weakness and fever up to 102. She felt sleepy, but slept well. No pain. Occasionally there was nose bleeding during the last weeks. Appetite was good. The well water of the family had during the summer a peculiar bad taste and odor, so that it was necessary to discontinue its use.

Status præsens; September 27, 1913: young lady, 18 years old, body weight (in light summer clothes), 114 pounds. Moderately nourished, very pale with a yellowish tint, no icterus. About the right corner of the mouth a few yellowish crusts from herpes, covering an exulceration. Mucous membranes of the mouth very pale. Right tonsil swollen, its lower pole with a cone-shaped yellowish projecting lobe (leucemic infiltration), left tonsil hypertrophied. No palpable lymph glands on neck, in axilla, or in inguine. No heart murmur. Liver: dullness of percussion sound in the mamillary line from the upper border of fifth rib down to the height of the umbilicus. The consistency of the liver somewhat increased, the border distinctly palpable. Spleen: The upper border by percussion in the anterior axillary line at the lower border of the seventh rib. Lower pole of spleen palpable in the mamillary line down to the horizontal umbilical line. Temperature 99° to 100.6°; blood, 2,620,000 erythrocytes; 38 per cent. hemoglobin; 76 per cent. color index; 15,150 white cells; 9 per cent. small mononuclear cells; 82 per cent. large; 7 per cent. polymorphonuclear; 1 per cent. eosinophiles; 1 per cent. transitional cells. Benzol-therapy. September 28: White cells, 12,800. Maximum temperature 105.4°. Benzol. September 29: Eyelids edematous, a few small petechial spots on left foot. Nose bleeding, temperature, 100.8°-102.4°. Benzol discontinued. White cells, 6,000. September 30: Temperature 98°-100.8°-101°; slight nose bleeding, blood very pale, watery. The whitish projection of the lower pole of right tonsil had gradually disappeared. Skin very pale, alabasterlike. White cells: 3,100; 4 per cent. small mononuclear cells; 89 per cent. large; 5 per cent. polymorphonuclear; 1 per cent. transitional cells; one myelocyte in several slides. October 1: Temperature 101.6°-99.6°-101.8°. White cells, 2,800; blood culture negative both aerobical and anaerobical (Dr. Rosenow). October 2: Body weight (unclothed), 106.75 pounds, pulse 128, temperature 100.4°-103.4°. Spleen and liver somewhat smaller. Appetite good, sleep good. Subjective feeling comfortable. October 3: Red cells, 1,920,000; hemoglobin, 30 per cent.; white cells, 2,200; 4 per cent. small mononuclear cells; 91 per cent. large; 5 per cent. polymorphonuclear; 1 per cent. transitional cells; temperature 101.4°-105 2°. Started daily hypodermic injections of electrargol and inunctions of Credé's ointment. October 4: Liver smaller, markedly soft and difficult to palpate. Temperature 100.4°-103°. October 5: Liver and spleen smaller. White cells, 2,700. October 6: White cells, 2,800; 7 per cent. small mononuclear; 88 per cent. large; 4 per cent. polymorphonuclear cells; temperature 100 8°-103.6°. October 8: Red cells, 1,840,000; hemoglobin, 22 per cent.; white cells, 1,600. Patient had a peculiar sensation, in which she could not talk or move her right arm for a short time; recovered fully from the attack. Serum albumin in urine positive. Temperature 101°-102.6°; pulse 120-128; respiration 28. October 9: Spleen much smaller; lower pole hard, reaching to the arch of the ribs. Patient very drowsy. Liver smaller, very soft and difficult to palpate. October 10: Temperature 100°. October 11: No fever, pulse very small and frequent, patient very somnolent; vomiting. October 12: Liver invalpable, spleen underneath the arch of the ribs. Soft murmur at the basis of the heart. Temperature 100°. Extreme pallor. October 13: Pronounced asthenia, collapse, vomiting; a few very pale punctiform hemorrhagic spots on body. Coma. Exitus at midnight.

Clinically there was no tumefaction of the lymph glands during the time of my observation. The swellings of the lymph nodes as known do not reach in acute leucemia such marked degrees as seen in the chronic forms and they may be even absent, as post-mortem findings have revealed. (Cases of Pappenheim, Walz, Reed, Kelly, and others.)

In the presence of leucemic blood pictures the condition represents—so to speak—the inversion of the symptom complex of lymphatic "pseudoleucemia." Pappenheim considers such cases of leucemic blood conditions with absence of tumefaction of the lymph glands as due to a primary affection of the bone marrow, causing through proliferation of its lymphoid cells the increase of the lymphocytes in the circulating blood, contrary to Ehrlich, who refers lymphemia to a primary affection of the lymph glands and only myelemia to an affection of the bone marrow. However, also in normal-sized or slightly enlarged lymph nodes severe pathological changes have been occasionally found.

The drop of the leucocyte number in our case to a subnormal, markedly leucopenic level can of course not be ascribed to the use of benzol (that was administered for only two days and interrupted when a decrease was observed), but must be considered as spontaneous, as often observed in this disease. The energetic, elective effect of benzol upon the hematopoetic system, especially upon the leucocytopoesis, as studied particularly in chronic leucemia shows itself at the beginning as stimulating and only later and in larger doses—mostly after the end of the second week—paralyzing and inhibiting the leucopoetic function, causing finally a decrease of the leucocyte number. There was also no cogent reason nor clinical indication for the presumption of a secondary septic infection as complication. A culture taken from the blood was negative. No post-mortem was permitted to determine the pathological and anatomical conditions of the hematopoetic organs; and no blood count was possible during the last days of life. No definite answer can be given to the question, whether a profound anatomical or a functional exhaustion of the organs took place due to the primary (leucemic) infection, revealing itself in spontaneous marked oligocytemia, and going hand in hand with a general collapse.

Ewald observed in a case of generalized aleucemic hyperplasia a leucemic figure as low as 800 leucocytes; Betz in a fatal case of pneumonia with pneumococcus sepsis, 800 white corpuscles with prevalence of the ungranulated elements of bone marrow in the blood picture.

Luigi d'Amato saw in splenomegaly after malaria 2,000 and Sluka in acute lymphatic leucemia 2,000 leucocytes. Leucopenias of such low degrees are, it seems, rare. Several mechanisms come into consideration in the causation of this interesting condition, among them lessened activity of the hematopoetic organs, lessened cytogenesis by funcional insufficiency as, for instance, resulting from the effect of the toxins of typhoid and in anemia, pernicious anemia, agonal stage of peritonitis, starvation, etc., possibly also in the minor degrees of *x*-ray and radium effect, where a decreased cell production in indicated by a decrease of purin substances. In other cases the function is lessened on account of anatomical destruction of greater parts of the hematopoetic tissues; or an increased leucocytolysis may take place. The generally increased excretion of uric acid in the urine in aute leucemia is referable to an increased destruction of nuclein and is from histological and experimental observations to be regarded as partly the result of the increased breaking up of white blood corpuscles. The severe initial intestinal disturbances observed in our case represent, it seems, merely a part of the symptom complex of acute leucemia, having been preceded by pallor of the skin; and are most probably in no causal relationship to the use of the well water, as none else of the family showed any intestinal disorder at the time. Dyspeptic manifestations and loss of appetite are repeatedly recorded as initial symptoms of acute leucemia. They were present in the case published by me last year and in a 14 months' old baby seen by me a few weeks before the above described case.

UMBILICAL INFECTIONS.

By RAOUL L. VIORAN, B.A., B.Sc., Ph.D., M.D.,
CHICAGO, ILL.

AN important chapter in the treatises on Pediatrics, that has been somewhat neglected or not fully considered, is that of Umbilical Infections.

Charles Gilmore Kerley of New York says in regard to this subject: "The frequent appearance in private practice and in out-patient clinics of infants with umbilical polypi, granulomata, suppurating umbilical stump, or an eczema involving a considerable area about a moist, actively secreting umbilicus, etc.," is another proof of the contention that the comparatively common source of infantile infections has been, to a certain extent, neglected.

Although modern and up-to-date practitioners and specialists avail themselves to the fullest extent of all applied rules of asepsis and antisepsis, nevertheless this subject is of importance, for there is still much superficial or inconsiderate treatment of infantile infections, traced mainly to those of the umbilical cord and wound, which are oftentimes diagnosed too late, or treated symptomatically, without the necessary routine of a thorough diagnosis.

In dealing with the subject of umbilical infections, I eliminate umbilical hemorrhages as a whole, and the hernias, making mention only of these conditions for the sake of completeness.

Umbilical infections occur in the new-born, in two ways: (1) through the umbilical wound, after the falling of the cord, and before the complete cicatrization of the wound, and (2) through the umbilical cord.

Generally speaking, umbilical infections may be due to neglect in the proper treatment of the cord, such as handling of it with unclean hands, the use of non-aseptic dressings, severing of the cord with not strictly aseptic instruments, the use of an unclean ligature for the cord, the imperfect cleansing of the wound of septic material, infection with lochial discharge after delivery, through the bathing of the newborn, etc.

Infections of the umbilical cord are apt to occur previous to the drying or mummification (Filatow-Hassin) of the cord and wound, although cases are recorded in which instead of drying of the cord, putrefaction ensues, followed by gangrene and sloughing. This last occurs usually in premature and debilitated infants, and instead of the wound becoming cicatrized, it remains open and humid, thus establishing a cycle of infection and reinfection. Runge reports the frequent coincidence of umbilical disease and ophthalmia, the pus from the conjunctiva being carried to the cord—another etiological factor in the infections of the umbilicus.

In a general way infections of the cord or wound, are due to saprophytic bacteria and the condition may remain a local one, leaving a wound with exuberant granulation which is the means of the production of the so-called "umbilical fungus." Cicatrization takes place in all cases, sooner or later, but where infections occur, we must attribute them to lack of resistance of the new-born, or the presence of pathogenic microorganisms.

In dealing with the etiology we must consider also infections carried to the new-born by a diseased mother, often the cause of a severe umbilical infection. In these cases we must isolate the child, the treatment of the cord and wound being carried out by a person who does not come in contact with the convalescent mother.

Among the bacteria most frequently causing umbilical infections, I mention the streptococcus, the *Bacillus coli communis*, and the *Bacillus pyocyaneus*.

Infections of the cord and umbilicus may be superficial or deep, and the different changes occurring at the umbilicus we may classify according to their aspects and parts involved. I must mention in this connection: the umbilical fungus, in which the umbilical wound stands out prominently; the umbilical ulcer, in which there is an ulceration of the tissues surrounding the umbilicus proper; umbilical pyorrhea, in which the umbilical wound is filled by a septic secretion; omphalitis or acute umbilical cellulitis, and periomphalitis in which there is an edema of the parts surrounding the umbilical wound, which may lead in grave cases to phlebitis, erysipelas, umbilical arteritis, abscess of the liver, or suppurative peritonitis. General septicemia follows usually in cases where the umbilical arteries become inflamed.

I may mention further diverticulum tumor and mucous polypus, which are really one and the same condition, and which, according to Holt are associated with an umbilical fistula, formed by a prolapse at the navel, of the mucous membrane of Meckel's diverticulum or the remains of the omphalo-mesenteric duct. In cases of arteritis or phlebitis, the vessels undergo definite pathological changes, such as induration, thrombosis, etc. Degenerative processes following a general septicemia have been demonstrated at autopsies, where all organs of the body were found to have been involved, as for instance: lung infarcts, congested areas in the lungs, hypertrophied spleen; large, thick, and white kidneys; a pale, pink, marble-like liver; multiple abscesses of the liver, lungs, and spleen; seropurulent exudates of the peritoneum and pleuræ, etc.

The diagnosis of the condition can be established by the local visible changes, occurring at the umbilicus, the microscopical examination of the umbilicus and umbilical wound discharges, the presence of icterus, especially immediately after birth, loss in weight, and the general bad condition of the infant.

Umbilical hemorrhages, that are constant and severe, after eliminating the case of a badly ligated cord, or after its dropping, are generally attributed to hereditary syphilis, and should be investigated carefully and tactfully. The treatment is that of syphilis elsewhere.

Other diseases of the umbilicus are the hernias. The majority of them are congenital, and are considered by Kerley to be due to failure in the closure of the ventral laminæ, or to a defective development of the parts at the umbilical opening, which give way under pressure, as in colic, strain in whooping-cough, etc. The treatment of these conditions is mechanical, and can be summed up in the injunction: reduce and prevent recurrence.

In case of putrefactive changes in the cord, when it becomes soft and greenish, it is advisable to use antiseptic powders such as boracic acid, tannic acid, quinine, bismuth, either one alone or combined, covering with plain aseptic gauze and the abdominal binder. I have used in two cases, previously handled by midwives, thymol iodide powder, and it proved excellent, more so in one of the cases in which there was a slight hemorrhage.

In cases of a profuse fetid discharge, it is recommended first to wash the parts with a solution of potassium permanganate 1-1000, dry well with absorbent cotton or plain gauze tampons, and powder with zinc oxide.

In cases of omphalitis and periomphalitis, it is sufficient to use warm boracic acid dressings, to be changed every 2 to 4 hours, according to the severity of the case, and never to use phenol or its preparations; I do not use corrosive sublimate either, as it is irritating to the delicate skin of the infant.

Pfaundler of Munich, and Schlossman of Dusseldorf, recommend for this last condition: moist compresses of liquor alumni acetatis (P.G.) diluted about eight times, or aq. plumbi (P.G.), diluted twice, together with the opening along a grooved director of any abscesses that may be present. Others advise a wet dressing of 1-5000 bichloride of mercury, changed every two hours. The potassium permanganate treatment can be continued for a few days, and the results are satisfactory.

In cases of lymphangitis or phlegmons, the same treatment is to be followed, with one exception and that is: where there are circumscribed abscesses around the umbilicus, they should be incised as soon as mature and then the wet dressings applied.

For the treatment of umbilical pyorrhea, simple and not complicated, a boracic-acid wash, drying, and dusting with an antiseptic powder will suffice.

In cases of ulceration, besides washing with boracic acid or hydrogen peroxide solutions, it is

found necessary to touch the wound and especially its margins,with tincture of iodine or with liq. iodi compositus or Lugol's solution.

For the fungous variety of umbilical pyorrhea, besides the initial wash, it is necessary to touch the fungosities with silver nitrate solution (2 per cent.), or the silver stick, about twice a day. W. L. Carr of New York, after cleansing with normal salt solution, ligates the mass if large, and if small, he destroys it by one or two applications of the actual cautery. From the standpoint of practicability and that of the general practitioner, the treatment above outlined seems more readily feasible.

The umbilical gangrene which follows putrefactive changes in the cord, may heal under the same treatment as outlined above, and leave a cicatrix; however, when the process is not limited and the gangrene appears after the falling of the cord and extends rapidly, presenting a bright, red tumor, with crepitation underneath, due to the evolving of gas from anaërobic microorganisms, no treatment is available; lavage, incision, and even the actual cautery are valueless; peritonitis is the usual sequence and the termination is fatal.

Cases have been recorded in which, besides the involvement of the peritoneum, the sphacelus or the putrid liquefaction of the tissues of the abdominal parietes, has reached a loop of intestines and induced a more rapidly fatal issue. Notwithstanding these facts, the condition should receive careful attention, and be treated as indicated, no matter what the prognosis may be, for wonders happen quite often.

Septicemia may occur as a sequel to a local infection or without any apparent local cause. Nervous symptoms associated with collapse, yellowish-white skin, irregular temperature, now high, now subnormal, with great variations in short intervals of time, chills, subcutaneous petechiæ (usually over the abdomen), sometimes ecchymosis and rarely serous or subcutaneous abscesses, are the evidences of our inability to meet the condition with any distinct or efficient treatment, as the condition is generally fatal, the case terminating by death in a few days from the onset.

Infantile erysipelas, is in many ways different from that of the adult, for in the newborn the spreading of the streptococcus infection is not limited to the superficial layers of the derma and the papillary layer, but it infiltrates and diffuses, invading the subcutaneous fatty tissues, lymphatic vessels, and especially the perivascular lymphatic sheaths, which are greatly developed in the newborn, as has been demonstrated by histologists. Erysipelas is more complicated and extensive in the newborn than in the adult, and phagocytosis is practically absent in the infant, in contrast to its marked development in the adult.

Before describing the treatment of this condition, I may make a digression and give a brief description of the development of this condition. The onset of the umbilical variety of erysipelas in the newborn is sudden, and occurs usually about the first or second week after birth; it is ushered in by a marked rise in temperature and the appearance of a red patch, which is not around the umbilicus but in the pubic triangle or sometimes in the hypogastric region; the child nurses well, and there seems to be nothing wrong with it. The temperature however rises, going up to 105° and 106° F., and is fluctuating. The patch extends rapidly to the penis and scrotum in boys, and labia majora in girls; the patch looks red, indurated, and shining; the abdominal patch extends, the skin becomes red, and the entire abdomen becomes involved and of a tumefied appearance. The eruption spreads and it is interesting to know that it does not follow a line of contiguity, but appears in patches here and there, uniting at last. There is no regularity or uniformity as to the parts that become involved first. Following the eruption, it is to be noticed that the redness fades and the spotted skin begins to desquamate. The temperature at this stage varies between 96.5° and 103° F., with marked fluctuations and great irregularity and with disproportionate pulse beat and rate. The infant becomes now torpid and quiet; its weakness increases hourly, it can no longer nurse; the temperature of the body becomes subnormal, falling lower and lower and the infant succumbs 6 or 7 days from the onset of the disease. In rare cases the eruption is not so virulent and in some recovery takes place. Of good prognostic significance is the presence of subcutaneous abscesses, an indication of the localization of the process; the abscesses being incised and the pus evacuated recovery often results..

As to the treatment: first, we must consider the antistreptococcus serum, which should be used in all cases of erysipelas, malignant or benign, with the understanding that it is to a certain extent harmless, that negative results are preponderating, while positive results can not be wholly attributed to its action. The antistreptococcus serum we must presume less efficacious in infants than in adults, for there appears to be a natural antagonism in the infant body, to the formation of antibodies, the phagocytic power being almost nil. The treatment with erysipelas phylacogen, has been reported to have been more efficacious; but notwithstanding the reports as to its success we must be reserved in approval of a preparation that is in the experimental period as yet. It should, in my opinion, be given repeated trials, and in justice to our patients cases of actual benefiting by it should be carefully recorded and fully reported.

Local applications of warm boracic acid compresses, changed every hour or two, using in addition, antiseptic dusting powders in cases of maceration of the skin. Ichthyol, having petrolatum as a base, is frequently used as a dressing, changing it every three to four hours. The strength of the ointment varies from 20 to 40 per cent.

The treatment of bronzed hematuria, a condition which is said to have its origin in an infected umbilicus, is symptomatic. The disease is characterized by an old copper-yellor coloring of the skin, shading to olive-green, and it is classed among the fatal diseases.

Another important condition resulting from an infection of the umbilicus and amenable to treatment is tetanus of the newborn, a disease due to the bacillus of Nicolaier. Tetanus of the newborn develops usually about 6 to 10 days after birth; the umbilical wound is of a grayish, dull, and moist appearance. The treatment of this condition consists in the immediate use of the antitetanic serum, which is very efficacious, not to say curative. Interesting to know is the fact that in the Isle of Madagascar, the disease was formerly as prevalent as scarlet fever in this country, and yet, with a preventive treatment of all the newborn with the antitetanic serum (500 units), the disease has been entirely eradicated there. It is advisable that the

serum should be injected before the contractions have set in. The doses of the serum must be large and the injections should be repeated every 24 to 36 hours. The initial dose should be the largest, that is of possibly 1500 units, the others, in proportion to the severity and duration of the disease. The injections in the newborn may be made intracerebrally, that is to say the needle is introduced through the lateral angle of the big fontanel and a small quantity of the serum slowly injected into each cerebral hemisphere. To the serum treatment we must add antispasmodic and hypnotic remedies, such as potassium or sodium bromide, in doses of 1 gram (16 grains) a day, per month, or a combination of bromide and chloral, aa 0.5 gram (8 grains), twice a day per rectum in decinormal salt solution; or in severe cases of contracture, chloroform inhalations, by the drop method, bearing in mind the important fact that complete narcosis should never be attained, as our innocent patient may never awake from it.

1601 South Kedzie Avenue.

OCCLUSION OF THE INFERIOR MESENTERIC ARTERY.

By E. DAVID FRIEDMAN, B.S., M.D.,

NEW YORK.

INSTRUCTOR IN MEDICINE AT UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE.

Embolism and thrombosis of the superior mesenteric artery are fairly common occurrences, and references to this subject in the literature are quite numerous. Similar processes, however, in the inferior mesenteric have been observed but rarely. I have found but one reference to the subject in our own literature—that of J. W. Elliott. Merkel collected six cases (including that of Elliott) up to 1911. To these he added his own case and those of Jürgens and Schnitzler. So that all told, the reported cases are few indeed. Partly because of the rarity of the condition, and partly because, as I believe, the diagnosis was correctly made *intra vitam*, I shall report the following two cases, which, curiously enough, occurred in two members of the same family.

Case I.—Adolph J., 44 years old, grocer, married. His wife had had no abortions. There were three healthy children. His father died at 78; the mother is alive at 75; one brother died at 49. His history will follow: One brother has attacks of intermittent limp. One sister has gone through four pregnancies, and had to be treated for toxemia of pregnancy every time. These facts show the predisposition of the family to vascular affections. Habits: Has always worked hard, smoked moderately, took alcohol moderately; venereal disease denied. Previous history: Had measles in childhood, smallpox at 16; otherwise negative up to eight years ago. Since then he is complaining of headache, vertigo, vomiting, and disturbances of vision. He was told that he had kidney disease. These symptoms recurred at irregular intervals. April 30, 1913: Sustained an injury to the left side of the skull; became unconscious one hour later, vomited, and had convulsions, Jacksonian first, later generalized. He was operated on, and a depressed fracture and extradural hemorrhage were found. He made a good recovery. He passed bloody urine one year ago, and again four weeks ago. (Renal infarction? Essential hematuria?) He now complains of pain in the legs. There is no history of intermittent claudication. He gets up at night to urinate. His appetite is fair, his bowels regular, and he has no cough. March 3, 1914: Physical examination—Patient poorly nourished and pale, his face showing pock-marks. The pupils, equal and round, react to light and accommodation. The beard growth is scant. The axillary hair is scanty, and the pubic hair is female in type. His throat shows pale mucous membrane; tonsils not enlarged. There are a few glands in the posterior cervical region; epitrochlears palpable. Neck: Heaving carotids. Lungs: A few fine râles at both bases. Heart: Apex beat 4 space, heaving in character. Aortic second, sound accentuated. Peripheral arteries, sclerotic. Blood pressure: 250 systolic, 170 diastolic. Abdomen, negative. Dorsalis pedis, thickened. Extremities, no edema. Knee-jerks, normal. No Babinski, Oppenheim, Mendel-Bechterew, or Rossolino. Urine: 1500 c.c.; albumin, trace. Sugar, negative; specific gravity, 1016. Microscopical, hyaline casts. Fundus: No signs of albuminuric retinitis. A blood smear showed a moderate chloranemia. March 8: The patient complained of a sharp pain in the abdomen, colicky in character, chiefly over the left side. There were no typical radiation, no vomiting, and no increased frequency of urination. The bowels had not moved on this day. Physical examination showed no rigidity. Pulse 84, temperature 99. There was some tenderness over the descending colon. A digital examination of the rectum revealed nothing abnormal. Stool ordered saved. Gave patient morphine and atropine. March 9: Pain less marked. The patient passed what was practically a blood cast of the large bowel. He complained of tenesmus. There were no shreds of mucous membrane in the evacuations, no feces, just clotted blood. Proctoscopic examination showed enormously congested mucosa with hemorrhages. No ulceration was seen. The patient had a number of bloody evacuations after that. Gave him 20 c.c. of normal horse serum; ice bag to abdomen. March 10: Less blood passed by patient to-day; status remains unchanged. He feels weak. March 14: The stools became lighter in color, and the patient gradually improved. After several days there was no more blood, macroscopically, although the aloin test was persistently positive. Pain, gone. There were at no time symptoms of intestinal obstruction or peritonitis. There now followed over a month of apparent comfort. The patient said he felt well. The Wassermann test gave a negative result. April 22: The patient developed severe precordial pain and dyspnea, and died from a rapidly fatal pulmonary edema (coronary thrombosis?)

Case II.—Samuel M. J., 46, marker, married; wife had one early abortion; had seven children, four now alive and well, the others having died in infancy. A married daughter suffered from toxemia during her first pregnancy. Habits: Patient for a long time smoked 15 to 20 cigarettes daily; took liquors in moderation; worked hard all his life. He was very irascible; venereal disease denied. The patient complained of headache, pain in the back and visual disturbances; had to get up at night to urinate; passed bloody urine a number of times. Physical examination: Patient was poorly nourished and pale; showed signs of status lymphaticus. The pupils react to light and accommodation. The throat shows enlarged tonsils; the neck a few enlarged glands. There were marked pulsations in the carotids. Lungs, negative. Heart, heaving apex, beat in the fifth space, with a systolic murmur at the aortic area and a loud aortic second. The blood pressure was 230 systolic and 140 diastolic. Abdomen, negative. Urine, limpid; specific gravity 1010. There was a faint trace of albumen; no sugar; a few hyaline casts. The knee-jerks were normal; dorsalis pedis, feeble. Fundus; hemorrhages in left eye, above and to left of papilla. December 21, 1911: The patient complained of "cramps" in the abdomen, especially around the navel. There was no radiation and no vomiting, but a pain in the back, especially on the left side. Physical examination showed tenderness over the descending colon. December 22, 1911: The pain was still present, but not so marked. The temperature was 98.6, the pulse 72. There was some tenderness in the left epigastrium; no melena. A proctoscopic examination showed very much engorged mucosa; no hemorrhages or ulceration. There were no hemorrhoids. December 23, 1911: The patient had a sinking spell last night, and passed a bloody stool. Temperature 98; pulse 84. The pain had gone, but there was still tenderness over the descending colon. December 24, 1911: No stool to-day; the patient vomited a dark brown fluid. The aloin test of the vomited material was positive. December 26, 1911: The abdomen was distended. There was no stool for 72 hours (paresis of the bowel?). Low enema brought bloody stool. December 28, 1911: The feces returned after enema, were lighter in color; the aloin test still positive. January 1, 1912: Temperature 98.6; pulse 72. Feces light in color (patient on milk

diet); aloin test negative, and improvement was steady. January 28, 1912: General condition of the patient good. September 16, 1912: Patient developed right hemiplegia with motor aphasia. There was neither unconsciousness nor vomiting, but some vertigo. (Cerebral thrombosis.) The Wassermann test proved negative. The patient gradually recovered power, and the motor aphasia partly improved. January 9, 1913: Patient had fulminating apoplexy; fatal in six hours.

The great similarity in the history of these brothers is striking indeed. In both there was the premature atherosclerosis, probably on the basis of congenitally poor tubing (Osler); and in both, the syndrome of inferior mesenteric thrombosis. The colicky pain, the tenderness over the descending colon, the rectoscopic picture, the bloody evacuations, the tenesmus, the absence of symptoms of ileus or peritonitis, appear to me to justify the diagnosis, even in the absence of co mplete post-mortem records. The hematemesis in case II need not disturb us, for Gerhardt's case too had gastric hemorrhage, and at the post-mortem examination the inferior mesenteric alone was found occluded (retrograde peristalsis).

While occlusion of the superior mesenteric usually leads to signs and symptoms of peritonitis or ileus, associated with bloody stools, closure of the inferior mesenteric is of less serious moment. It causes a transitory disturbance in the circulation of the lower bowel, with symptoms referable to the colon, diarrhea, bloody stools and tenesmus. Some cases may show no symptoms. The latter is more apt to be the case in slow occlusion, with the possibility for the establishment of a free collateral circulation. So long as the heart and blood vessels are sound, the anastomosis is of value. When, however, the vessels are atherosclerotic or the heart decompensated, the symptoms are fairly definite. The anatomic changes vary. There may be mere hyperemia of mucous membrane. There may be necrosis of superficial tissues, leading to embolic ulceration which then heals and leaves a stenosis in its wake. Finally the process may involve the entire wall of the gut, leading to perforation and peritonitis. Gerhardt[1] reports a case of interior mesenteric occlusion in the course of decompensated valvular lesion. There was no pain, just gastric and intestinal bleeding. Hegar's[2] case followed myomectomy. Patient showed colic, vomiting and diarrhea; later there were foul bloody stools. Antemortem there was a subsidence of symptoms. In Pinner's[3] case there was sudden diarrhea, vomiting, and collapse. Three days later stools became bloody. Adenot[4] reports a case occurring in the course of a generalized atherosclesosis. Three days before death there was collapse with diarrhea. No blood was passed. Elliott's[5] case also was one of atherosclerosis. Patient developed colic, abdominal distention, followed by bloody stools. He considers a chronic endarteritis as having been the cause of the occlusion. Ritterhaus[6] reports a case occurring during the course of a decompensated valvular lesion; patient also showed atherosclerosis. Three days before death there was pain in the left side of the lower abdomen. No bloody stools were passed. Jürgens[7] reports a case occurring during the course of a mitral stenosis (where embolism is so common). Schnitzler's[8] patient had attacks of pain in the abdomen. Bloody stools appeared on the last day of life. Merkel's[9] case was one of atherosclerosis. The patient showed pain in the left side of the abdomen, but no vomiting. Bloody stools appeared, and there was tenderness over the descending colon. Fleiner[10] reports the case of an atherosclerotic individual who suddenly developed colicky pain and tenesmus, and passed a large fluid stool, consisting, according to his description, of "pure blood." Digital examination of rectum showed only blood on end of finger cot. No hemorrhoids were present. Rectoscopy practiced several days later revealed nothing. (Collateral circulation well established?)

Diagnosis: We must think of these accidents in all cases of the so-called acute abdomen. We must exclude organic disease of the bowel (gastric and duodenal ulcer) and portal obstruction and thrombosis. A careful watch should be kept over the stools and rectoscopy should be practised in all cases suggesting abdominal angina or atherosclerotic colic. The etiological factor may be cardiac disease, atherosclerosis, endarteritis (lues). In the case of a patient with valvular disease, who had previously shown no gastrointestinal symptoms, one would think rather of embolism. In the case of an individual with atherosclerosis, contracted kidney, and hypertension, with associated sclerosis of the splanchnic vessels, we would think rather of thrombosis. Some cases may show only a sudden pain with partial collapse, then the symptoms disappear. In these cases we should think of mesenteric occlusion and examine the feces for occult blood.

I might append the words of Kussmaul, who first made the diagnosis of embolism of the mesenteric arteries. "This diagnosis is to be made when, under circumstances permitting the assumption of embolism, symptoms of intestinal bleeding, enteritis, or peritonitis occur, without there being any other cause for these accidents. The hemorrhage will be absent when paralytic meteorism supervenes." In the diagnosis of inferior mesenteric occlusion, early rectoscopy should be of value.

In conclusion, I wish to thank Dr. Benjamin Jablons, pathologist of the Har Moriah Hospital, for the examination of the blood cast in case I.

The "Bruit de Galop" in Typhoid Fever.—J. Mallard and A. Dumas state that when this sign appears late in the course of a severe case of typhoid fever it is evidence of an atrophy of the myocardium. If the cantering rhythm appears in the acute stage it indicates an affection of the myocardium, but only the very beginning of this process, for if the myocarditis becomes more pronounced the bruit will disappear with the weakening of the heart.—*Revue de Médecine.*

A CASE OF GIANT CELL SARCOMA SUCCESSFULLY TREATED BY A COMBINATION OF SURGERY AND THE X-RAYS.

By EDGAR BIRDSALL, M.D.,

GLENS FALLS, N. Y.

ROENTGENOLOGIST, GLENS FALLS HOSPITAL.

CURES of sarcoma have been previously reported by Pfahler and others. The report of the following case was withheld until a sufficient length of time had elapsed to warrant any positive claims for the action of the rays.

CASE.—J. H., age 55; married; 3 children. No family history of malignancy. Had been in good health until the summer of 1910, when a small mass appeared in the neck on the right side, just below the angle of the jaw. This was diagnosed as an enlarged gland and non-interference was advised.

The mass increased in size so rapidly that both physician and patient became alarmed and it was removed. A microscopical examination proved it to be a giant cell sarcoma.

Within a period of less than four weeks another small mass appeared in the neck and *x*-ray treatments were advised. The mass measured about 2 inches in diameter and was freely movable. Two erythema doses, in a series of twelve treatments each, were given. A filter of heavy sole-leather was used and an interval of four weeks was allowed between each series.

At the end of the second series the mass was about ½ inch in diameter. A severe dermatitis then appeared and further treatments were considered inadvisable. The remaining mass was again removed.

Immediately following this operation, the patient contracted a severe attack of erysipelas which kept him in bed for about two months. During this period another small mass appeared and as soon as he was able, he returned for *x*-ray treatments. This time the mass entirely disappeared.

During the following year the patient returned for observation at intervals of about six weeks. There was no evidence of a recurrence.

It is now three years and a half since the last treatments were given and the patient is apparently in fine health. The incident of the erysipelas seemed to cloud the issue in the mind of the surgeon and he was inclined to give it the credit for arresting the disease. Inasmuch as recurrence took place during and after the attack of erysipelas and the growth was not checked until after *x*-ray treatments were again begun, his opinion was, I think, not well founded.

Medicolegal Notes.

Sale of Medical Practice—Agreement Not to Practice—Rescission by New Contract.—A physician sold his practice to another, under an agreement whereby he agreed not to practice medicine in that town. The seller prepared in good faith to quit his practice as agreed, and did all in his power to turn it over to the purchaser. The latter, however, being shortly afterwards informed that another physician thought of locating in the town, proposed to the seller to enter into a copartnership for the joint practice of their profession. The seller agreed, and a new agreement was entered into for a partnership for three years. This new contract was complete in itself and did not refer in any way to the old contract. The partnership continued for over 8 months, when it was dissolved by mutual consent. The seller of the practice under the old contract continued in the practice of his profession in the town. The purchaser brought an action for damages and for an injunction. It was held that the two contracts were quite inconsistent with each other, and the second therefore abrogated the first, so that it was not revived on the dissolution of the partnership. The seller's agreement to become the purchaser's partner was held to constitute a sufficient consideration for releasing him from the prior agreement not to practice medicine in the locality.—Menefee v. Rankins, Kentucky Court of Appeals, 164 S. W. 365.

State Medical Board—Uncertainty of Statute.—The Colorado statute, Rev. St. 1908, §6068, authorizes the State Board of Medical Examiners to revoke a physician's license for certain specified acts, one of which is "obtaining a fee on the representation that a manifestly incurable disease can be permanently cured." In proceedings under the statute alleging that the defendant obtained a fee by representing that he could permanently cure a person of consumption, knowing the disease to be at the time incurable, it was held that the words "manifestly" and "incurable" applied to the disease and not to the person or the condition of the person afflicted with the disease, and, there being no disease known and understood to be manifestly incurable, the statute was to this extent void for uncertainty. Conceding that the words did relate to the condition of the patient, the statute was held to be still too indefinite and uncertain to form the basis of a judgment for the revocation of a physician's license. Three judges dissented.—Graeb v. State Board of Medical Examiners, Colorado Supreme Court, 139 Pac. 1099.

Authority of Officers of Corporation to Employ Medical Aid.—A corporation's foreman called its general manager on the telephone, informed him of an injury to an employee, and that he had called in three physicians. The general manager, in the presence of the president of the corporation and after consulting with him, told the foreman to employ competent physicians to perform the necessary operation (the amputation of both hands as the result of an explosion), and have them attend and care for the employee. In an action by the three physicians against the corporation for their services, it was held that their employment was authorized, and the corporation was liable for their services, since, whether or not a general manager has authority to employ a physician to treat an injured employee, there is no doubt of the president's authority to do so.

The employee's testimony that the general manager had offered to compromise his claim for injuries, and said that he would pay the doctors $100 for their services, was held to be admissible, the employee not representing any of the physicians, and not being their agent to effect any compromise for them.—Newberry v. Missouri Granite & Construction Co. (Mo.), 163 S. W. 570.

Examination of Medical Experts—Questions.—In a passenger's action for injuries from the collision between interurban cars, which hurled her against the back of a seat, producing, it was alleged, a diseased ovary, physicians testified directly from their own knowledge of the plaintiff's condition, which knowledge was derived from treatment and examination of her injury. It was held that questions put to them were not objectionable because they failed to include the facts bearing on the state of the injured part of her body. To the extent, at least, of their knowledge derived from personal observation, the questions propounded were not strictly hypothetical questions; and it was therefore unnecessary that they contain all the essentials of a hypothetical question.—Millirous v. Missouri & K. I. R. Co. (Mo.), 162 S. W. 1069.

Hypothetical Questions—Province of Jury.—A physician was asked a hypothetical question whether a prolapsed condition of one of the ovaries and an anteverted condition of the womb could be caused by injuries resulting from a woman, who was sitting in a street car when it was derailed, being thrown out of her seat with considerable force, and receiving a blow in the region of the thigh, and also receiving a bruise on the leg and an injury to the hip. He stated that a falling forward in a street car was liable to bring about an anteversion of the womb, which was constructed in the manner stated, and that a falling forward thereof causes a displacement of the uterus. Another physician was asked a question, to the effect that, supposing the evidence showed that a passenger was riding in a street car when it jumped the track onto the ground with some force, and she was thrown from her seat forward so as to receive a bruise on her hip and groin, "Would you say that such a falling as that would cause a prolapsed condition of the womb or the condition that you found there the first time?" The witness answered that an accident of that kind might produce a dropping down of the womb, and that such anteversion "could be" caused by the accident. It was held that the answers to these hypothetical questions did not usurp the province of the jury, in that they stated a conclusion rather than the opinion of the witness.—Patterson v. Springfield Traction Co. (Mo.), 163 S. W. 955.

MEDICAL RECORD.

New York, October 24, 1914.

CEREBRAL COMPLICATIONS AFTER LIGATION OF THE COMMON CAROTID.

THE immediate operative mortality after ligation of the common carotid has been variously stated, the minimum being Crile's estimate of 3 per cent.; but there is cerebral softening or some other intracranial complication in approximately 25 per cent. of the cases, while about one-half of those that develop cerebral trouble die. Among the causes of death are shock, excessive hemorrhage, or some other factor dependent upon the nature of the operation, anomalies in the vessels usually forming the avenue for compensatory collateral circulation, thrombosis, embolism, and sepsis. Gilson-Herman (*Ann. de la Soc. Belge de Chir.*, March, 1914), after describing a very interesting case of arteriovenous aneurysm affecting the internal carotid and internal jugular, in which the common carotid was successfully tied, enumerates some of the different theories in explanation of the cerebral troubles that so frequently occur after this ligation, and advances a theory of his own. Among the theories quoted are the following: Friedländer believes that the cause is a change of the direction of the blood and of the hydrodynamic forces in the circle of Willis; Guinard contends that the brain is not subject to immediate lesions if there are collaterals in sufficient number, while the phenomena which make their appearance later, would be the consequence of progressive thrombosis, of emboli due to arteriosclerosis, or of infection; Kocher and also Mendès say that success depends chiefly upon the state of the arteries, and counsel not attempting ligature in the presence of arteriosclerosis; De Fourmestreux affirms that cerebral troubles do not follow except in the presence of infection.

To determine the extent and modus operandi of the collateral circulation, Gilson-Herman made a number of experiments upon the cadavers of newborn children, injecting a fluid opaque to the *x*-ray. Besides injecting after tying the common carotid alone, injections were also made after the common carotid, vertebral, and inferior thyroid arteries were tied on one side. *X*-ray plates were taken after all these injections, in the lateral as well as in the anteroposterior directions. In all instances the fluid found its way to all parts of the body, even when the vertebral and inferior thyroid had also been tied off. By examination of the plates and by dissection it was determined that when one makes the injection at the level of the arch of the aorta, after ligature of the common carotid, the liquid reaches the brain through the basilar trunk, proceeding by way of the posterior communicating artery to the internal carotid on the side which is tied, and as that is empty a flood of material takes place into it. This is well shown by the *x*-ray plates and in this engorgement lies the basis of this theory.

The same phenomena, Gilson-Herman believes, takes place in the living after ligation of the common carotid, and he thinks the great mortality of the operation may fairly be ascribed to this cause. As a matter of fact, when one ties the common carotid the portion distal to the ligature becomes momentarily deprived of blood. The artery, being an eminently elastic element, contracts and expresses a part of the blood which it contains into the different collaterals, then dilates. A negative pressure is thus produced in this part of the carotid. But a regular deluge of blood then comes along by way of the posterior communicating and internal carotid, and there is formed a veritable whirlpool. Besides, when the collateral circulation becomes established blood comes in great quantity to the external carotid, and this increases the whirlpool existing in the common carotid. It is not improbable that this abnormal circulation may detach and disintegrate the clot formed at the site of ligature and thus bring about fatal embolism. It is to be noted that embolism is the most frequent accident and that it habitually occurs many hours after the ligation. As the author says, proof of this phenomenon (we should say theory) should rest upon the most precise experimental basis; and we are promised that the attempt to furnish such proof will be made.

STREPTOLYSIN.

OF all the pathogenic microorganisms with which we are acquainted, the streptococcus is probably the cause of a greater variety of disease conditions than any other. The organisms gathered under this name, moreover, include a very great number of strains, some of which resemble each other apparently only in their morphology. The streptococci have proved a tempting field for research, but the yield has not been proportionate to the labor expended. The matter of classification, never satisfactorily settled, has been perilously near an upset as a result of Rosenow's work. Nevertheless, Lyall has endeavored (*Journal of Medical Research*, XXX, 1914) to separate them on a basis of their biological reactions. A characteristic of streptococci is their reaction to red blood cells, tested usually by growing the organisms on blood agar plates. Lyall has revived a method originally described by Marmorek in which a definite amount (0.5 c.c.) of an 18-hour calcium carbonate ascitic broth culture of the organism is added to 10 c.c. of a 5 per cent. emulsion of washed sheep's corpuscles and incubated one hour at 37.5°. Three distinct types of reaction occur in: (1) The hemolytic group which dissolve the cells and which

correspond to the *S. pyogenes, vulgaris*, or *hemolyticus;* (2) the methemoglobin producers which change the color of the undissolved cells from a bright red to a dark brown by the production of methemoglobin; (3) the indifferent group in which there is neither hemolysis or change in color. When grown on blood agar plates both 2 and 3 produce green pigment. The *Streptococcus viridans* is characteristic of group three. According to Lyall the sugar reactions of these groups are quite constant.

The production of a lytic substance is characteristic of a large group of these organisms and he tried to see if there was any consistent relation between virulence and lysin production. He found that while those strains isolated from the blood were usually most actively hemolytic, there was no recognizable relation between the severity of the disease and the hemolytic power of the strain. In the course of his investigation, however, he discovered some interesting facts concerning this streptolysin. It is apparently quite closely united to the bacterial cell since it will not pass through a coarse Berkefeld filter, and agents which bring about the death of the organism also deprive the emulsion of its hemolytic properties. It is destroyed by heating to 56° for 30 minutes, but does not behave like an enzyme. Its production is favored by the enriching of the media with ascitic fluid. One of the most interesting points which he was able to demonstrate was that normal serum of man as well as that of several animals contained appreciable amounts of an antistreptolysin and that this inhibiting power was tremendously increased by giving the animal salvarsan before obtaining the serum. This action was out of all proportion to any minute amount of arsenic which the serum might contain. The carbohydrates also act to inhibit hemolysis and of these glucose is the most powerful.

These observations open tempting fields for speculation in the line of therapy. Although it cannot logically be argued that an antistreptolysin will cure a streptococcemia, nevertheless there is a chance that an agent which inhibits one of the functions of an organism, may in some way injure the cell and thus help to bring about a cure. It seems probable that the ultimate remedy will be one that stimulates the body to the production of efficient antibodies, whether it be by the administration of vaccines or by some other method yet to be devised.

The Benzol Group and Hematopoiesis.

Benzol as a remedy in the treatment of leucemia has attracted considerable attention within recent years, but there has been some difference of opinion as to the real action of benzol upon the leucocytes. Pappenheim has advanced the view that these are not destroyed by benzol, but are only made to accumulate in the capillaries of the internal organs and especially in those of the liver. On the other hand G. B. Bianchi claims to have demonstrated an actual leucopenia evoked by benzol as well as a severe aplasia of the bone-marrow and an atrophy of the spleen and of the enire lymphatic apparatus. In *Pathologica*, August 15, 1914, the same observer reports the results of his experiments undertaken with the view of determining the effects of other hydrocarbons belonging to the same group as benzol, namely, toluol, xylol, and cumol. Although these substances bear a close resemblance chemically to benzol, they have a different effect upon the leucopoietic apparatus. This effect is an excitatory one, being manifested by a leucocytosis. In daily doses of one to two cubic centimeters per kilogram of body weight, these substances cause in the rabbit a leucocytosis associated with a hyperplasia of the bone-marrow, an hypertrophy of the spleen, and a slight enlargement of the lymphatic glands. It has been noted by Selling that in certain cases the first injection of benzol causes a slight leucocytosis. This is interpreted as evidence of an initial excitatory phase in the action of benzol. Bianchi suggests that the other aromatic bodies studied by him might in larger doses have an action similar to that of benzol, namely, an irritative phase followed by one in which depression and atrophy are pronounced characteristics.

Pineal Gland Deficiency Symptoms.

These are fairly well known in so far as they depend on tumors of the gland, although under such circumstances we could also think of a dyspinealism, from the analogy of the hypophysis, in which plus and minus symptoms occur side by side. In recent years notes on tumors of the pineal gland have accumulated until we have fifty-six recorded cases which comprise sarcomata, gliomata, and teratomata. Most of these cases show correspondence to a fixed type, the subjects being young individuals with marked longitudinal growth, abnormal distribution of hair, enlarged genitals, and sexual precocity. In some cases there is also psychical precocity. To a certain extent this syndrome is coherent, and suggests that deficiency of pineal secretion enables a hormone from some other endocrinic body to stimulate growth and development. At a session last summer of the Aerztlicher Verein of Munich (*Berliner klinische Wochenschrift*, September 7) Schmincke, from whose article the above notes are cited, presented two cases of tumor of the pineal gland from young women of twenty-one and seventeen years of age respectively. One of these was an example of so-called three-leaved or trefoil teratoma.

Rectal Aerophagia.

This curiosity of medicine is exemplified in the case reported by Taillers in the *Archives des Maladies de l'Appareil Digestiv et de la Nutrition*, January, 1914. The patient was a nervous impulsive girl of fifteen years, in whom an extreme flatulence was found to be caused by the habit of rectal aerophagia. The girl would assume the genu-pectoral position, in which the intestines would gravitate toward the upper part of the abdomen. The resulting vacuum in the lower abdomen and in the pelvis would create suction. At the same time there would occur an active relaxation of the anal outlet. As a result air would be sucked into the anus, thus completing the phenomenon of rectal air-swallowing. The author states that the same practice is sometimes indulged in by European soldiers as a pastime or game while they are off duty in the barracks or in camp. In this martial sport the winner is the one who at the greatest distance can blow out the flame of a candle by means of the air expelled from the rectum!

News of the Week.

Appointment of a State Medical Inspector of Schools.—The New York State Civil Service Commission invites applications for appointment as State Medical Inspector of Schools, Education Department. Salary $5,000 per year. Open to men only. Applicants for this position must be graduates of a college approved by the University of the State of New York. Applicants must also have had at least five years' experience in the practice of medicine in this State and must also show at least three years' experience in public health inspection. Applicants must also show a reasonable familiarity with the general organization and administration of the public school system. Preference will be given those who show important experiences in public health and sanitation work and who have had experience in public speaking upon health propositions. Candidates will not be required to appear at any place for written examination. They should be careful to set forth their training and experience in full in their applications. They may be summoned for a personal interview with the examiners.

Convocation of the University of the State of New York.—At the fiftieth convocation of the University of the State of New York held in the Education Building, Albany, on October 22 and 23, the program for Thursday included an address on "What Is a Profession?" by George Herbert Palmer, L.H.D., LL.D., Alford Professor of Natural Religion, Moral Philosophy and Civil Polity (Emeritus), Harvard University. Discussion of this topic was led by Robert Abbe, M.D., New York City; Adelbert Moot, LL.D., Buffalo; Edward C. Kirk, D.D.S., Philadelphia, Pa., and William M. Polk, M.D., New York City.

Brooklyn Pediatric Society.—At the meeting of this Society to be held October 28, in the building of the Medical Society of the County of Kings, 1313 Bedford avenue, the paper of the evening will be on "Tonsillotomy *vs.* Tonsillectomy," by Dr. Thomas R. French. The paper will be discussed by Dr. D. Bryson Delavan, Professor of Laryngology in the New York Polyclinic; Dr. Henry L. Swain, Professor of Laryngology in the Medical School of Yale University; Dr. G. Hudson Makuen, Professor of Laryngology in the University of Pennsylvania, and others.

Medical College of the University of Vermont.—There has been some talk of discontinuing this institution, but at the meeting of the State Society held during the first week in October the proposition was rejected by a vote of 78 to 1.

Proposed Revision of the Kansas Medical License Law.—At the request of the Kansas State Medical Association, Governor George H. Hodges has appointed a committee of five to suggest amendments to the present laws governing the practice of medicine in Kansas. The members also are commissioned by the governor to suggest a codification of the medical laws of the state, if they think it advisable. The following have been appointed on the commission: Dr. J. A. Milligan of Garnett, Dr. J. E. Sawtelle of Kansas City, Dr. W. L. Burdick of Lawrence, Fred Dumont Smith of Hutchinson and F. T. Ransom of Wichita.

Dr. Bulkley's Dermatological Clinics.—The governors of the New York Skin and Cancer Hospital announce the annual course of lectures by Dr. L. Duncan Bulkley on Wednesday afternoons at 4.15 o'clock. The course this year will be devoted to the "Medical Aspects of Cancer." The following are the titles of the lectures: November 4, nature of cancer; November 11, frequency and geographical distribution of cancer; November 18, metabolism of cancer; November 25, relation of diet to cancer; December 2, medical treatment of cancer; December 9, clinical considerations and conclusions. Each lecture will be preceded by a half-hour clinical demonstration of dermatological cases. The lectures will be free to the medical profession, on the presentation of their professional cards.

Vermont State Medical Society.—At the one hundred and first annual meeting of this Society held at Rutland on October 8 and 9, the following officers were elected: *President*, W. W. Townsend of Rutland; *Vice-President*, W. J. Ricker of St. Johnsbury; *Secretary*, J. M. Hamilton of Rutland; *Treasurer*, C. F. Dalton of Burlington; *Auditor*, E. M. Brown of Sheldon. The next meeting will be held in Burlington, October 14 and 15, 1915.

Wisconsin State Medical Society.—At the annual meeting of this Society, held in Oshkosh on October 8 and 9, the following officers were elected: *President*, Dr. T. J. Redlings of Marinette; *First Vice-President*, Dr. H. E. Dearholt, Milwaukee; *Second Vice-President*, Dr. Spencer Beebe, Sparta; *Third Vice-President*, Dr. H. W. Morgenroth of Oshkosh; *Delegates to American Medical Association*, Drs. A. H. Levings of Milwaukee and J. F. Pember of Janesville.

Norfolk, Va., County Medical Society.—The following officers were elected at a meeting of this Society held October 5. *President*, Dr. E. T. Hargrave; *Vice-President*, Dr. J. J. Miller; *Secretary and Treasurer*, Dr. W. P. McDowell, reelected.

Connecticut Eclectic Medical Association.—At the fifty-ninth semi-annual meeting of this Society in Hartford on October 13 the following officers were elected: *President*, Dr. James E. Hair of Bridgeport; *Vice-President*, Dr. H. H. Converse of Eastford; *Secretary*, Dr. Thomas S. Hodge of Torrington; *Treasurer*, Dr. Thomas Mulligan of New Britain.

Prevention Inoculation of Soldiers.—Typhoid fever is said to be practically non-existent among the French troops owing to the fact that antityphoid inoculation is compulsory in that army. The French recruits of the class of 1915, which is being organized, have been invited to take advantage of the free antityphoid vaccination that will be supplied before they join the colors instead of waiting until after they are enrolled in the army. Among the Germans, however, this measure was never so enthusiastically approved and the result is there are many cases of typhoid reported by a Dutch physician among the Germans in the army of the west. The troops of the Allies are also, it is said, inoculated against tetanus before being sent to the trenches. A large order for tetanus antitoxin has been placed in this country by the British government.

English Physicians to the Front.—The British War Office has appointed Sir John Rose Bradford, Sir Wilmot Herringham, and Sir E. Almroth Wright consulting physicians with the British expeditionary forces in France. The three physicians, who will have the rank of Colonel, left England this week, accompanied by three expert bacteriologists.

Americans Donate Ambulances to the Red Cross.—A dispatch to *The Sun* from London says that the American residents of that city have

equipped ten motor ambulances under the auspices of the British Red Cross. They will probably serve under British control at Amiens. Most of the donors will drive the cars themselves, accompanied by mechanics.

Cholera in Austria.—It is reported from Rome that there are several thousand cases of cholera in Galicia and Hungary, and that the Russian army has withdrawn from Hungary, repelled by the comma bacillus rather than the Austrian bullets.

Bequests to Charities.—By the will of the late Charles H. Whitright of Philadelphia an estate of $3,000 is to revert on the death of his widow to the Orthopedic Hospital and Infirmary for Nervous Diseases for the endowment of a free bed.

By the will of the late Robert H. Crozer of Upland, Pa., the sum of $200,000 is bequeathed in trust for the organization of a corporation to maintain a hospital in Upland or Chester to be conducted under the "allopathic" system; also the sum of $5,000 is bequeathed to the Women's Hospital of Philadelphia in trust, the income to be devoted to maintain a free bed; also the sum of $5,000 is bequeathed in trust for the maintenance of a free bed in the Philadelphia Home for Incurables.

By the will of the late Isaac Cohen of Philadelphia the sum of $500 is bequeathed to the Jewish Hospital of that city.

Addition to Municipal Nursing Service.—Provision has been made by Philadelphia Councils for the installation of ten additional nurses in the Division of Child Hygiene of the Department of Public Health and Charities.

Personal.—Dr. W. J. Aldrich of St. Johnsbury is the candidate for governor of the Progressive Party of the State of Vermont.

Dr. Louis Livingston Seaman has resigned his commission as first lieutenant Medical Reserve Corps, U. S. A., in order to be free to tell of what he had seen of the horrors of war in Belgium, President Wilson having forbidden officers of the Army and Navy to comment on the situation.

Dr. HENRY S. GOODALL, the superintendent and medical director of Stony Wold Sanitarium at Lake Kushaqua, has resigned, to take effect on December 1. Dr. Goodall has been connected with Stony Wold for the last ten years during which time the number of patients at the sanitarium has increased from forty-five to one hundred and six.

Dr. ALBERT C. THOMAS, for many years assistant superintendent of the Connecticut State Hospital and later superintendent of the New Haven Hospital, has been appointed superintendent of the Foxboro, Mass., State Hospital.

Dr. ANTHONY TRAILE, provost of Trinity College, Dublin, since 1904, and the only medical man who ever occupied that post, died October 11, at the age of seventy-six years.

New York and New England Association of Railway Surgeons.—The twenty-fourth annual meeting of this Association was held at the Hotel Astor, New York City, on Wednesday, October 21, under the presidency of Dr. C. A. Pease of Burlington, Vt. The secretary is Dr. George Chaffee, 338 Forty-seventh street, Brooklyn, N. Y.

State Board Examinations.—Hereafter the New York State Board of Medical Examiners may ask candidates questions on the duties of practitioners under the Sanitary Code established by the State Public Health Council, and also on the duty of reporting industrial diseases under the Labor Law.

Hospital Notes.—A two-story addition to the Bridgeport, Conn., Hospital has just been completed; it will be used for surgical work, the surgical ward being on the ground floor and the anesthetizing and operating room on the floor above.

The Winyah Sanatorium at Asheville, N. C., was destroyed by fire on October 2. The institution was for the treatment of tuberculosis and was under the care of Dr. von Ruck.

Dr. Simon F. Cox, formerly superintendent of the Boston Hospital for Consumptives, has been appointed superintendent of the New Haven Hospital to succeed Dr. A. C. Thomas, resigned.

The tuberculosis camp of the New York Throat, Nose, and Lung Hospital is ready to receive patients for the winter. Only moderately advanced cases in men are received.

The James Buchanan Brady Urological Institute was opened October 9. This is the third of the "special units" for general hospital work that have been erected to form part of the Johns Hopkins equipment. The building is seven stories in height and contains departments of bacteriology, chemistry, and pathology, as well as a museum, laboratories, and clinical amphitheater.

Obituary Notes.—Dr. ALEXANDER MARTIN HERON of Lakewood, N. J., a graduate of the Medico-Chirurgical College of Philadelphia in 1899, and a member of the American Medical Association, the Medical Society of New Jersey, and the Ocean County Medical Society, died at his home on October 11, aged forty-nine years.

Dr. JEDEDIAH MARCUS BARTON of Worcester, Mass., a graduate of the Hahnemann Medical College and Hospital, Philadelphia, in 1870, a member of the American Institute of Homeopathy, and a former president of the Worcester Homeopathic Medical Society, died at his home, after a long illness, on September 30, aged 69 years.

Dr. ERVING A. LIBBEY of Cranston, R. I., a graduate of the Medical School of Maine, Portland, in 1897, and a member of the Providence Medical Society, died at his home, after a short illness, on October 7, aged thirty-nine years.

Dr. GEORGE BROWN REYNOLDS of Baltimore, Md., a graduate of the Washington University School of Medicine, Baltimore, in 1872, and a member of the Medical and Chirurgical Faculty of Maryland and the Baltimore City Medical Society, died suddenly while hurrying to a patient, on October 2, aged 68 years.

Dr. FRANK M. THOMS of Lansing, Mich., a graduate of the University of Michigan, Department of Medicine and Surgery, Ann Arbor, in 1891, and a member of the American Medical Association, the Michigan State Medical Society, and the Ingham County Medical Society, died at his home, after a long illness, on October 5.

Dr. MADISON M. HOLLAND of Statesboro, Ga., a graduate of Vanderbilt University, Medical Department, Nashville, Tenn., in 1884, died at his home on September 30, after a long illness.

Obituary.

JAMES GREGORY MUMFORD, M. D.

CLIFTON SPRING, N. Y.

Dr. JAMES GREGORY MUMFORD of Clifton Springs, N. Y., died on October 18. Dr. Mumford was born in Rochester, N. Y., on December 2, 1863, and was educated at Harvard University, receiving the de-

gree of A. B. in 1885 and of M. D. in 1890. He was appointed assistant surgeon to Carney Hospital, Boston, in 1892, and assistant surgeon to the Out-Patient Department of the Massachusetts General Hospital in 1894, and in 1896 became assistant in surgery in the Harvard Medical School, advancing to the position of instructor in 1903. In 1905 he was made visiting surgeon to the Massachusetts General Hospital, serving in this capacity until 1912, when he resigned to become physician-in-chief to the Clifton Spring Sanatorium and Hospital, a post which he held at the time of his death. From 1892-93 he acted as surgeon in the Naval Brigade of the Massachusetts Volunteer Militia, and also served as surgeon in the Medical Reserve Corps of the United States Army. He was a fellow of the American Surgical Association, the American College of Surgeons, and the Massachusetts Medical Society, and a member of the American Medical Association, the Boston Society for Medical Improvement, the American Society of Clinical Surgery, of which he was also secretary, the Surgical Club of Boston, the Boston Obstetrical Society, The Boston Medical Society, the Boston Society of Medical Sciences, and the Société internationale de chirurgie, as well as of the Hasty Pudding Club of Harvard and the University Club of New York. Dr. Mumford had written largely and always entertainingly on many phases of medicine, among the better known of his books being the "Narrative of Medicine in America," 1903; "Surgical Aspects of Digestive Disorders," 1905; "Surgical Memoirs and Other Essays," 1908; "Practice of Surgery," 1910, with a second edition in 1914; and a "Doctor's Table Talk," 1912.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

OPENING OF WINTER SESSION AT THE MEDICAL SCHOOLS—LECTURES AT MIDDLESEX HOSPITAL—PROTECTION OF NEW BORN INFANTS AND MOTHERS—WAR NOTES—OBITUARY.

LONDON, October 2, 1914.

THE winter session of our medical curriculum opened yesterday. The metropolitan hospitals and schools observed the day for the most part in the traditional manner. Some of the provincial schools delay a day or two and the Scottish colleges open a month later. It is most convenient for the student to begin his curriculum with the winter session, which is a sufficient reason why the "opening day" has for so many generations been devoted to the "first year's man." The introductory lecture, which still continues to inaugurate the work at most schools, was designed in his interest, serving as a medium for advice as well as information on the special advantages of his chosen school and his wisdom in selecting it. Occasionally this point of view has been forgotten or but slightly touched upon, the lecturer occupying most of his time with a subject interesting enough to his colleagues and former students who may be present but hardly adapted for the freshman.

Older students at many schools have been accustomed to celebrate the opening day by a dinner, at which practitioners educated at the college often put in an appearance as visitors. But on account of the war such reunions are being canceled for this year.

The opening of the session at the Middlesex Hospital School aptly illustrates the foregoing remarks. The lecture was delivered by Dr. Hubert Bond, who seized the opportunity of dealing with some points in the management of mental derangement. He complained of the difficulty of filling junior posts in asylums, which he attributed to the decrease of those considered to be the plums. Some local authorities had substantially improved the conditions, and he thought they were within measurable distance of the time when no resident whom it was desirable to keep should be debarred from marriage or other social advantages. Several universities had instituted diplomas in psychiatry and these it was to be hoped would soon be followed by clinics. But to establish them the sympathy and help of the general hospitals was necessary, but he only knew of the Mandsley that had done anything in this direction. Specialties in general hospitals have come to stay, but the gamut is not complete without psychiatry. Yet not one general hospital can boast a clinic on this subject. If there were such clinics and out-patients departments in connection with them he felt sure that many a mental breakdown could be prevented. The Middlesex professed to cater to every branch of medicine, but a gap existed as it did at every other general hospital. It would be in accord with its highest and best traditions if the Middlesex were to lead the way.

Recent legislation has made considerable additions to the provisions which have long been in operation for the care and protection of the new born infant as well as of the mother during parturition and some time after. Both the local Government and the educational boards have authority to dispose of certain sums granted by Parliament for assisting institutions which meet the necessities of a large class of mothers whether in maternity hospitals or by securing them prompt attendance in their homes by midwives or when needed by further help. It is now announced that "schools for mothers" will receive grants in aid as will dispensaries, special hospitals and infirmaries, baby clinics, maternity clinics, and any other institutions or associations founded by voluntary efforts or depending more or less on State or municipal aid. Some weeks ago the local government board brought the subject under the attention of the local authorities who desire to avail themselves of the proposed State grants, and Dr. Newsholme, their medical officer, suggests arrangements for (a) supervision of midwives, (b) provision for attendance at the mother's delivery at her home, or in special cases at a maternity hospital, (c) superintendence of the infant, and medical treatment as may be required at home or at clinics, dispensaries, or other institutions. You will observe that these proposals do not conflict with the work of existing organizations, public or private, and no difficulty will arise as the change is rather to extend the sphere of their work than to supersede it; while it will give it the increased importance attached to State authority and assistance. The extension of the work will probably be greater than anticipated with a tendency to grow. In regard to the mother it is proposed to include the period of pregnancy and another period subsequent to childbirth—perhaps lactation—in the sphere of operation. In regard to the infant it is intended for the superintendence to continue up to the time of entering the first school, whether a nursery school or other.

The scheme has attracted less attention than might have been expected, but some disapproval is being expressed, especially by those politicians who oppose almost every interference of the State with the individual or the family as savoring of socialism. One such declares that the work was being very well carried on by voluntary associations who are to be superseded by an additional organization with the usual increase of cost entailed by public control. Another opponent insinuates that the plan of working by subsidizing the institutions engaged was adopted as the only means of reconciling them to the change.

The names of medical officers continue to be reported among the lists of killed, wounded, and missing arriving regularly from the seat of war.

A number of surgeons, nurses, and orderlies have gone and others are going over to France under the auspices of the British Red Cross Society. This society is also arranging in cooperation with the automobile club to send one hundred motor ambulances.

The Fishmongers' Company have furnished their magnificent hall as a hospital for wounded officers.

Sir Henry Duncan Littlejohn, late President of the Royal College of Surgeons of Edinburgh, Professor of Medical Jurisprudence in the University, and for a generation the recognized leader in matters of public health, died September 30, at the ripe old age of eighty-six. Through his long professional career he has been occupied with sanitary science. For nearly half a century he was Medical Officer of Health for Edinburgh, and his report in 1865 on the sanitary condition of that city stamped him as a leader of sanitary reforms. He was knighted in 1895, a tardy and inadequate recognition of his great public services. He was medical witness for the Crown in all the important criminal cases of his time, and his lectures were often illustrated by the points raised in the trials in which he had been engaged.

Dr. Charles Steele, consulting surgeon to the Royal Infirmary, Bristol, died September 20, aged seventy-six. He qualified at the two London colleges in 1860-61, proceeding to the F.R.C.S. in 1869, and adding M.D., Durham, in 1880. He had an extensive practice in Bristol and Clifton and was much trusted by his brethren in consultations. Besides the surgeoncy of the infirmary, he held that of the local Children's Hospital and was for some time a lecturer in the medical school. His chair supports for spinal curvature and some other inventions are well known, and he contributed freely to the medical journals.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

INCREASE IN CHOLERA—SEARCH FOR CHOLERA VIBRIO CARRIERS—FILTHY RAILROAD TOILETS AS CAUSES OF INFECTION—BUBONIC PLAGUE IN HONG KONG—RISE IN FOOD PRICES CAUSED BY THE EUROPEAN WAR—MAJOR MUNSON ACTING HEALTH OFFICER IN MANILA.

MANILA, August 12, 1914.

A SHARP rise of cholera has occurred during the past month, spreading from Manila northward along the railroad as a result of temporarily incomplete and ineffective measures for control. Manila itself is showing an average of but one or two cases a day, but the problem is particularly perplexing because of the high proportion of healthy persons who are found bacteriologically to be "carriers" of cholera vibrios and whose occupations may be such as to render them particularly liable to convey their infections to others. Thus in one day three handlers of cooked food in native restaurants were found to be carriers. In another series, of one hundred and sixty-nine persons coming to autopsy from causes other than cholera, seven were found to be cholera carriers. In fifty-three persons taken at random from an infected district, eight were found bacteriologically positive for cholera. Of twenty-six contacts with a tuberculosis case found to be a cholera carrier, nine were found to be carriers also. A very high proportion of cases presenting disorders of the intestinal tract, as dysentary, tuberculous ulceration, diarrhea, etc., appear also to be true cholera carriers. As a result of these healthy and other carriers, there is a constant upcropping of cholera cases, but as yet in no instance developing into a local epidemic. The cases are scattered and the measures taken are usually entirely and promptly effective in preventing the development of further cases from these foci. The problem now seems to resolve itself into considering the frank cases of cholera as merely the expression of latent conditions in the healthy population, the cause of which can only be removed by the detection and isolation of the healthy harborers of the cholera vibrio. This, for a population of approximately a quarter of a million, is a task of herculean proportions. However, it will probably suffice in practice if the carriers of the most dangerous class can be reached and quarantined, and this especially dangerous class is undoubtedly to be found in the handlers of cooked food in tiendas and the kitchen forces of hotels, clubs, boarding houses, restaurants, ice cream parlors, etc. Plans are under way to examine all members of this class of persons, and the Bureau of Science is making examinations at the rate of some eight hundred per day. As a result, reports show that nearly a hundred carriers are constantly in quarantine at the cholera detention hospital. Many cases have been removed from hotels and other places where their presence was liable to start local epidemic outbreaks at any time. Most of the carriers seem to clear up in about two weeks under the use of saline catharties and intestinal antiseptics like salol—though how much real value the latter possesses for the purpose is problematical. Cases are held in quarantine until negative to two examinations several days apart. Examinations are based on cultures made from feces, or from swabs taken from the rectum, and given the agglutination test.

A tendency of cholera cases to gradually crop up along the railroad north of Manila has led to an investigation of the privy closet facilities at the railroad stations. Out of one hundred and sixty-three stations, only fifty-eight had closet facilities, fifteen of the latter were closed, and of the forty-three in use only twenty-four were reported as being fairly good as to surroundings. Most of those in use were found to be open to flies. In many of them the waste disposal methods were ineffective. In the majority of cases, the closet was found to be kept locked as a convenience for the station master and his family only. As a result, the vicinity of almost every station was found fouled by human deposits, and as food exposed to flies was sold at many stations, the possibility of transmission of infection introduced by carriers and disseminated by flies and food was very great.

The Public Utilities Commission has taken up the matter, and is forcing the railroads to install and maintain proper privy closet facilities. The results of this inspection make one wonder if the toilet facilities at small stations on the railroads of the United States would appear to good sanitary advantage if given similar sanitary inspection. Your correspondent has a vivid recollection of the insanitation and nastiness of some of them, especially in the South.

In a recent series of four thousand nine hundred and eighty apparently healthy persons, resident in Manila, the Bureau of Science has found one hundred and sixty-five to be "carriers" of cholera vibrios. This means that about three per cent. of the general population may be regarded as distributors of the cholera infection. This proportion seemed to hold good in the various sanitary districts of the city, though, as far as actual cases are concerned, the incidence of the disease is much greater in districts north of the river than south of it. No American has as yet been found to harbor the disease germs, and but relatively few Chinese; and likewise the actual cases of the disease are almost exclusively among Filipinos. The disease itself occurs almost wholly among the lower class Filipinos, among whom the standard of personal cleanliness is low, and who eat their food from common dishes into which all put their usually dirty fingers. Of course these "carriers" are an imminent danger to even the most careful individuals and households, for personal care cannot offset the danger from "carriers" among apparently healthy servants. The Bureau of Health has therefore issued a warning requesting all householders, in addition to their own personal hygiene, to see to it that servants habitually wash their hands after visiting the toilet and before handling food.

The last health report from Hong Kong states that since January 1, 1914, that city has had 2,136 cases of bubonic plague, with 1,986 deaths therefrom. The fact that Manila is now kept almost entirely free of plague, though the seven epidemics of 1901-1902 indicate that this city presents an environment most favorable to the development of plague infection, is very conclusive evidence as to the efficiency of the preventive measures being employed. The difference is more notable since in Hong Kong any degree of compulsion can be employed in the repressive measures, while here they are really dependent upon public approval and good will.

One immediate result of the outbreak of the European War was a sharp rise in prices of certain foodstuffs, especially canned milk. In forty-eight hours the price in Manila rose from nineteen to thirty-six centavos per can. As practically no fresh milk is available in these islands, the people are dependent on the canned variety and any interference with the supply of the latter must have a strongly prejudicial effect on the mortality of children. With the low scale of wages prevailing over here, it is a financial strain on the lower classes to buy canned milk for their children even at the former low prices. Hence even a slight increase in cost may remove milk from the reach of a very considerable portion of a Filipino community. To meet the needs of the situation, the Governor General was appealed to, and the latter announced that the Government would enter into the sale of milk for the purpose of keeping down prices. The military authorities placed some six hundred thousand cans of milk at the disposal of the Government at cost for this purpose, and sales of milk, in small quantities to each purchaser, were made in all the public markets and stations of the Bureau of Health in Manila. The selling price was fixed at what would yield a fair profit to the dealer, as the idea of the Government was not so much to sell milk as to leave the trade in the hands of the usual dealers and use Government participation in the business merely as a means of lowering prices. As a result, the inflated price of thirty-six centavos has fallen to an average of about twenty-four centavos.

Dr. Edward L. Munson, surgeon and major in the United States Army Medical Department, who has been appointed Acting Director of Health for the Philippine Islands in the place of Dr. Heiser, who has gone to the United States on a long leave of absence, has arrived in Manila from Zamboanga, where he has been serving as health officer for the Moro country and established and put into operation an effective sanitary organization among its lately hostile people. Dr. Munson is not unfamiliar with the work of the Bureau of Health, as he was on duty therewith a number of years ago and served as Acting Commissioner of Health in 1903-1904. He is the author of a number of books on hygiene and sanitary work, and has been teacher in these subjects in the army schools in Washington and Fort Leavenworth. Dr. Munson has many old friends in Manila, and it is understood that his selection as health officer was favored by the Filipinos, whose support and confidence he had acquired during his previous tour of health work among them.

Dr. W. E. Musgrave gave a beautiful dinner at the Manila Hotel complimentary to the new Acting Director of Health, at which thirty guests were present. The latter included Secretary Denison, Commissioner De Veyra, and the prominent American and Filipino medical men of Manila. There were no formal speeches.

1. Epidemiological Features of an Outbreak of Paratyphoid Fever (*Bacillus paratyphosus alpha*). M. M. Canavan.
2. Clinical Features of an Outbreak of Paratyphoid Fever. M. E. Gill-Noble.
3. Notes on the Blood Cell Picture in Paratyphoid Fever and after Vaccination with *Bacillus typhosus*. M. M. Canavan.
4. Note on the Relation of Paratyphoid Fever to Antityphoid Vaccination. M. M. Canavan.
5. Conclusions from Work on the Paratyphoid Fever Epidemic at the Boston State Hospital, 1910. E. E. Southard.

1. Epidemiological Features of an Outbreak of Paratyphoid Fever.—M. M. Canavan states that this epidemic consisted of about 30 cases of a mild form of paratyphoid fever which occurred at the Boston State Hospital, between October 19 and December 1, 1910. There were no deaths. The epidemic was confined largely to employees, although a few patients were also affected. The first indication of a disease of a typhoidal nature was obtained by the discovery of a positive Widal reaction in a female patient assisting in the serving-room of the nurses' quarters. From the blood of this patient actively motile organisms were recovered. One of the male patients who was an assistant in the preparation of food and had for one of his duties the turning of the meat machine, was found to have fever (101°); from the blood of this patient the *Bacillus paratyphosus alpha* was cultivated.

3. **The Blood Cell Picture in Paratyphoid Fever and After Vaccination with Bacillus Typhosus.**—M. M. Canavan states that leucocyte counts may prove of some service in differentiating paratyphoid from typhoid fever, since counts show that the paratyphoid blood picture remains within the normal range, (a) without a tendency to hypoleucocytosis at any stage of the disease and (b) without loss or drop in the eosinophiles. In interpreting this result it must be remembered that the epidemic from which these data were derived was one of mild paratyphoid fever (*Bacillus paratyphosus alpha* type). The blood cell picture after antityphoid vaccination remains within the normal range, with a tendency to a slight initial rise in leucocytes.

5. **Paratyphoid Epidemic at the Boston State Hospital.**—E. E. Southard states that apparently the source of the epidemic was infected meat or else a patient with paratyphoid infection may have spread the epidemic through meat. The clinical features of the epidemic were of great interest. Initial fever was practically constant. Anorexia, diarrhea, abdominal pain, general malaise and vomiting were not as frequent as they usually are in typhoid fever. Of the special modes of onset bronchitis was frequently noted. In the course of the disease stiff joints occurred in 19 out of 30 cases of paratyphoid fever, whereas in typhoid fever arthritis is rare. Four of the patients suffered from muscle pains in the back of the neck. Malaria was suspected in one case from the nature of the acute symptoms. There are points of interest in the temperature curves. A case occasionally has a beginning temperature suggestive of typhoid fever, but this is not the rule. The intercurrent bronchitis fails to affect the temperature reaction, being possibly a portion of the disease rather than a truly intercurrent phenomenon. Insane patients show some differences in fever reactions to various infections from the reactions shown by sane persons. Eight cases in 30 showed a peculiar drop of temperature to subnormal in the second or third week—as a rule between the tenth and fourteenth day. This temperature drop is accompanied by a drop in the pulse and by an access of the most severe subjective symptoms felt at any time in the disease.

9. The Present Status of Functional Liver Tests. E. B. Krumbhaar.

6. **Modern Treatment of Bright's Disease.**—J. Herold points out that free elimination by the skin, lungs, and bowels is of paramount importance in chronic interstitial as well as in chronic parenchymatous nephritis. Lung elimination is aided by fresh air, as is the anemia. The bowels are kept active by fruits, green vegetables, the coarser cereals, salines, cascara, senna, or aloes, and by occasional doses of calomel or of elaterin. The stomach should be invigorated by bitter tonics, the headaches relieved by bromides, and the anemia combated by a judicious use of iron and moderate exercise when the patient's health permits it. When the urine or urinary solids are deficient, digitalis, caffeine, potassium acetate, or theobromine sodiosalicylate may be employed. The prognosis of chronic nephritis is much less favorable than that of the acute forms, but if the strength is kept up and the quality of the blood is improved, life may be protracted and amelioration within certain limits may be attained.

7. **Substitution Reactions.**—By C. P. Oberndorf. (See MEDICAL RECORD, May 30, 1914, page 1007.)

9. **The Present Status of Functional Liver Tests.**—E. B. Krumbhaar concludes that although no satisfactory single test for the functional capacity of the liver has yet been accepted, the phenoltetrachlorphthalein test of Rowntree promises the greatest value. The levulose and galactose tests, though easy of application, are positive in too many non-liver cases to be considered reliable. The amount of urea in the blood or urine or its percentage to the total noncoagulable protein is totally unreliable in cases of cirrhosis or passive congestion. Like the tests for fibrinogen and lipase content of the blood, however, it may be of value in such obscure toxic conditions as phosphorus poisoning or acute yellow atrophy, where the great mass of liver cells is simultaneously and deeply involved. Tests for urobilinogen in the urine, increased permeability to methylene blue, positive Abderhalden reaction, and diminished glycolytic activity of the blood serum have also been described. The careful employment of one or more of these tests in the study of any given case of liver disease will unquestionably reveal facts of value. Further clinical and experimental work in this direction will probably furnish a diagnostic technique, the success of which is comparable to that employed in diseases of the kidney.

5. **Erythema Nodosum and Tuberculosis.**—O. H. Foerster states that from a study of the case reports now available in the literature it appears reasonable to regard the close association of erythema nodosum with tuberculosis in these cases as more than accidental. If one looks on erythema nodosum as an infectious disease due to a specific microorganism one can adopt the suggestion of Abt, that like other infectious disease as measles and pertussis it may act by preparing the soil for tuberculous infections. It has not yet been definitely established, however, that erythema nodosum has a specific cause, while there is experimental evidence to show that in some cases tubercle bacilli are present in the blood at the time of the eruption, and in

the lesions themselves. This would establish the tuberculous etiology of some cases of erythema nodosum, which can then be classed as symptomatic, along with the nodose lesions occurring in syphilis, gonorrhea, scarlet fever, and typhoid fever. Furthermore, Foerster maintains, every case of erythema nodosum occurring in young children with a family or personal history of tuberculosis should be regarded with suspicion and as perhaps indicative of the change of a latent or unsuspected focus of tuberculosis into an actively advancing process.

11. The Affinities of Beriberi and Scurvy.—S. T. Darling notes that Funk mentions five groups of symptoms observed in diseases caused by food theoretically deficient in vitamins: (1) Nerve degeneration with paralysis and contractures. (2) Cardiac: dilatation of right heart, dyspnea, cyanosis, oliguria. (3) Anasarca, hydropericarium, hydrothorax, ascites. (4) Scorbutus with mouth lesions, skin and subperiosteal hemorrhages, and bone lesions. (5) Pellagra syndrome, stomatitis, gastrointestinal lesions, skin erythema, and multiple nerve symptoms. The author believes that if it can be shown that scurvy, a typical example of a food deficiency cachexia, possesses certain pathological features identical with those of beriberi, about which the etiology in the minds of some is as yet undetermined, it will help to establish a place for beriberi among the dietetic cachexias. He had the opportunity of observing cases of scurvy on the Rand, South Africa, and his impression of these cases was that the disease is of an infectious nature, but this impression rapidly gave way to a confirmed opinion that it is due to dietetic errors. Not only has the Rand type of scurvy affiliations with beriberi, in that cardiac degeneration and degeneration of the vagus occur in typical scurvy as well as in beriberi, and by reason of the appearance of beriberi or neuritic features in certain epidemics of scurvy, but G. P. Turner of Johannesburg has observed that many of the negro miners dying of various diseases, at necropsy disclose slightly edematous calves without any other sign of scurvy or beriberi. Scurvy has definite affiliations with rickets, and infantile scurvy, too, for in the case seen at Bulawayo there had been extensive destruction of the chondrocostal junction, with depression of the entire sternum. Three severe cases of scurvy, practically free from complication (one had a little tuberculosis), came to necropsy at one of the Ancon hospitals. The anatomical findings were closely similar and are summarized in a composite anatomical diagnosis: Hemorrhagic extravasation into muscles of both legs, left forearm, and left psoas muscles, involving the muscle fascia between muscles, old and recent; subperiosteal hemorrhage, shaft of left femur; hemorrhage into left knee-joint; old subcapsular hemorrhage (knee-joint); ulcerative gingivitis with hemorrhages; separation of mandibular periosteum; anemia of all viscera; hypertrophy and dilatation of right heart; fatty degeneration of musculature of right heart; hyperplasia of femur marrow; edema of lungs, and scaly desquamation of both legs. The striking eccentric hypertrophy and dilatation of the right heart with extensive fatty degeneration of the same musculature, the left heart remaining apparently normal, and the severe degeneration of the vagus nerve described in several fatal cases of scurvy from the Rand, furnish new and additional facts which show the intimate relationship between scurvy and beriberi as to etiology. The presence of affinities between these two diseases (scurvy and beriberi) and certain other cachexias, Darling maintains, lends emphasis to the opinion that they are one and all the result of the continued use of a one-sided and deficient diet.

7. Ambulance Work in France. J. Donelan.
8. Dieppe as a Military Hospital Base. W. K. Sibley.

1. Application of Suturing to the Vascular System.—R. Warren points out that there are three main difficulties to be encountered in the practice of suturing blood-vessels: (a) Hemorrhage, which is overcome by very accurate suturing; (b) thrombosis due to the effect of interposing foreign bodies (in the form of sutures) in the blood stream—this ill-effect is minimized by the use of suture material steeped in liquid vaseline; and (c) infection, which leads to thrombosis and disintegration of the tissues sutured, and spoils all hope of success, indicating the need for the most rigid asepsis in these operations. Wounds of the heart fall into two main groups according to the size of the wound in the thoracic wall and pericardium. (1) Where the wound in the latter is large and widely open and there is a penetrating wound of the heart of any size, death from uncontrollable hemorrhage will be so speedy that opportunities for surgical interference can hardly arise, except in such exceptional cases as that described by Travers where the penetrating object remained in the wound and effectively plugged it. (2) A more usual condition is where the external wound is small and slitlike, as from a stab, and consequently the blood effused from the wounded heart cannot escape from the pericardium, but remains pent up in this cavity. The diagnosis of traumatic hemopericardium and "cardiac compression" rests on (a) finding a wound over the precordium, and (b) on the general symptoms of the patient, since local signs pointing to the condition, such as an increased area of cardiac dullness, diminished strength of the heart sounds, or adventitious sounds, may be quite unnoticeable. Where the signs point to hemopericardium only it will suffice to turn out a flap of soft tissues over the fourth and fifth right rib cartilages and the half sternum opposite these, removing the cartilages and half sternum. Where further injuries to lung, etc., are suspected it will perhaps be safer to employ positive pressure insufflation anesthesia and open the thorax widely along the fifth costal space, separating the ribs with suitable retractors. The fibrous scar resulting after the rib cartilages are removed is quite strong enough for practical purposes. Having exposed the pericardium the presence of blood is easily recognized by the tenseness of the sac, the impaired action of the heart, and the dark color of the contained blood seen through the translucent wall. When in doubt a small incision through the wall of the pericardium will permit egress to the contained blood, and if the patient's condition is bad will relieve the pressure on the heart. The next step is to open the pericardium freely and search for the wound in the heart; free bleeding may render this somewhat difficult. Having found the aperture it should be temporarily secured with catch-forceps and sutures passed taking up the whole thickness of the wall of the wounded portion. Ordinary silk sutures have proved successful, but to prevent thrombosis and pulmonary embolism vaselined sutures would be an improvement, since both cases coming under notice de-

veloped signs of embolism after some days. The pericardium should be closed without drainage, and the skin flap sutured in place, a drain tube passing down to the pericardium for 24 hours. Blood-vessels may be sutured for (a) injuries, (b) in the treatment of aneurysms, and (c) to reverse the circulation in parts where the arterial circulation is becoming impaired.

2. **The Value of Antistreptococcal Sera.**—J. W. McLeod draws the following conclusions: A certain type of streptococcus exists very virulent for rabbits and capable to a peculiar degree of producing toxin in the body of an infected animal, against which rabbits cannot be readily immunized, and that the serum of a horse treated with injections of these streptococci is not capable even in large doses of conferring passive immunity on the rabbit. A careful perusal of the literature with regard to antistreptococcal sera leads to the opinion that none of the sera available is likely to afford a supply of immune opsonin at once adequate in amount and sufficiently adapted to the strain of streptococcus involved markedly to alter the course of streptococcal infection in man. In the treatment of severe streptococcal infections normal heated horse serum, which has been proved slightly superior in the author's experiments, and which would in any case be cheaper and more easily preserved, might if administered in large doses, be substituted with advantage for commercial antistreptococcal serum. Experimental work on the therapy of streptococcal infections which aims at finding some artificial antibody to streptococcal toxin is much more likely to be fruitful than any further efforts to amend and improve the methods of immunizing horses to this type of bacteria.

1. **Surgical Treatment of Nephroptosis by Oclusion of the Perinephric Fascial Sac.**—C. B. Lockwood describes this operation as follows: The patient is placed in the usual position for nephrotomy with a sandbag or an inflatable air cushion between the table and the flank. An oblique incision is made about an inch below the twelfth rib, not quite parallel to it, but more in the direction of the fibers of the external oblique. The incision begins behind at the outer border of the erector spina and is carried forward for four or five inches. The length of the incison depends upon the thickness of the abdominal wall. The muscles are split in the direction of their fibers. No nerves are divided and the bleeding is trifling. The fascia transversalis having been opened the kidney is sought for. The author has found this step, usually a troublesome one, made quite easy by rolling the patient over until the wound faces the table. Then the finger is passed over the kidney to separate the perinephric fascia from the colon and peritoneum, and the perinephric fascia is taken between the finger and thumb at the lower end of the kidney, which is squeezed upward within its sac. When the kidney is gone up as high as is judged necessary the perinephric fascia is clamped at its lower end with pressure forceps and ligatures of No. 2 or No. 3 twisted silk are passed around it with a curved needle. The author has passed two and sometimes three of these silk sutures about half an inch apart. The ends of these ligatures are left long and used to fix the perinephric fascia to the abdominal wall. Before applying the pressure forceps the perinephric fascia is felt between the finger and thumb to make sure that the ureter is not being taken in. When the perinephric fascia has been ligatured the lower end of the kidney is at about the level of the twelfth rib and moving a little with respiration. The operation is completed by bringing the abdominal muscles together with chromic gut sutures and suturing the skin with silkworm gut. This operation hardly takes more than half an hour and is followed by very little shock, pain, or vomiting.

2. **The Use of an Aperient Before X-Ray Examination of the Intestine in Chronic Constipation.**—R. Gompertz and M. Scott conclude from their experiments that in chronic constipation the variations between the rates of passage of the bismuth along the intestine are but small whether the bowel has been emptied by a preliminary aperient or not; at the most the differences are not greater than can be said to be within the normal limits. Further, where differences were noted in the two series they were not constant, being in one case in the direction of greater rapidity after an aperient, in another of less, and in a third varying at different times in the same patient. It is, however, undoubtedly wise in most cases to give a purge before making an *x*-ray examination, on account, first, of the greater clearness of the skiagrams obtained when the intestine is empty; and, secondly, of the discomfort which the patient, deprived of his usual aids to defecation, may experience in the two or three days occupied by the *x*-ray observations, during which, of course, no aperient must be given. The result of the author's trials appears to show, nevertheless, that in cases in which time does not permit of a preliminary purge, or in which it is undesirable for any other reason to give it, the conclusions reached may be accepted without the fear that they have been materially vitiated by the omission.

6. **The Thymus Gland in Its Clinical Aspects.**—A. E. Garrod discusses the association of hyperplasia of the thymus with sudden death in children and adults. The subject is usually discussed under three headings—namely, thymic death, the sudden death of infants apparently healthy, apart from any antecedent signs of pressure upon the trachea; secondly, thymic asthma, a condition which may assume a more or less chronic form, or may manifest itself in paroxysms of stridulous dyspnea; and, thirdly, the condition known as status thymico-lymphaticus or status lymphaticus. Caution is needed in making the diagnosis of thymic asthma, and in some cases such a diagnosis made during life is shown to be incorrect post mortem. What is thought to be an enlarged thymus may prove to be an abscess around mediastinal glands, as in a case which Thursfield has described. Nor must it be forgotten that stridulous dyspnea in infants has several causes, such as enlargement of bronchial or tracheal glands, retropharyngeal abscess, membranous laryngitis, laryngeal spasm, and the abnormality of the larynx causing congenital stridor. Lastly, there is evidence that not a few cases of supposed thymic death have actually been due to suffocative bronchopneumonia. In some cases at least thymic asthma is due to pressure, but in others the stridor appears to be due to laryngeal spasm rather than to narrowing of the trachea. Paltauf brought the subject of status lymphaticus into the field of practical medicine and surgery. He presented the picture of a general constitutional state which predisposes to sudden

death from causes apparently inadequate and in which hyperplasia of the thymus is no longer the dominant feature but only one of a group of deviations from the normal. Not a few of the factors which go to make up the clinical picture are such as cannot be detected in the living patient. Such are the general enlargement of the intestinal follicles, the unduly small aorta, and the diminution of the chromaffin tissue, which may be the most important of all. Of the accessible signs special stress may be laid upon the hyperplasia of the lymphatic tissues at the root of the tongue, which may be seen with the laryngoscope and which is regarded by good observers as specially characteristic. Enlargement of the tonsils and adenoid vegetations are so common apart from status lymphaticus as to have little diagnostic value, and the same is true of slight enlargement of the lymphatic glands in the neck, axilla, and groins. An increase of lymphocytes in the blood is of similar service, and if it can be shown that the thymus is abnormally large this affords evidence of considerable value.

Lupus Syphiliticus.—Heinemann reports a case of that which was clinically ordinary lupus vulgaris, but which yielded to antisyphilitic measures. The skin of the external nose was reddened, swollen, and ulcerated. The lesion had persisted for seven years, and from the nose had extended to the upper lip. Former ulcers had healed with formation of large scars. The interior of the nose was covered with crusts, and there was a perforation of the septum. The condition had proved refractory to the usual antilupous remedies. The ulcers alone were not typical of lupus, and were more like those of tertiary syphilis. There is no mention of a Wassermann test. The prompt response to iodide of potassium convinced the author that the lesion was syphilitic. Under this medication the lesions underwent complete involution. A history of infection, dating back to three years before the appearance of the lesion, was obtained. To the iodide of potassium was later added an inunction cure. The author will also employ salvarsan, doubtless with the aim of obtaining a negative Wassermann reaction. Syphilitic lupus in the strictest sense of the term is a very rare affection. Patients suffer for years, as in the author's case, during which all antilupous remedies are tested in vain. Of great interest is a double case in mother and daughter, reported in 1910. The disease spread to the eyes before its true nature was recognized, causing total and partial blindness. The vision could have been saved had antisyphilitic measures been tested.

Certain Unknown Activities of the X-rays and Their Therapeutic Utilization.—Eckstein refers to the fact that as far back as 1896 the claim was made that the then newly discovered rays relieved the pain of cancer of the stomach. A year later Gocht stated that the rays relieved neuralgic pains. Animal experiments showed further that they depressed reflex excitability. Since those days the rays have come into such extensive use for organic disease that the undisputed fact of nervous sedation has either dropped out of sight or been set down to suggestion. The author has been at work on the subject for the past five years and has treated many painful conditions with relief of suffering. These include rheumatic and gouty pains, herpes zoster, neuralgia, and neuritis. Moreover spasmodic states like bronchial asthma and pseudo croup have similarly yielded, as has also paroxysmal cough of reflex character. There appears to be a direct action of the rays upon the terminal nerve filaments. Vasomotor crises also appear to yield in the same manner, as shown in a case of gastric crisis and angina pectoris. Finally various postoperative (postnarcotic) symptoms, such as pain and nausea, appear to derive benefit from the rays. No unpleasant collateral effects have been noted as a result of the treatment.

Action of X-Serum on the Blood.—Glaubermann of Moscow uses the term x-serum to denote blood serum which has been *x*-rayed, 8 c.m. of serum having been made to absorb 100 x. The idea of testing this product appears to have originated with Wermel during the present year, and already it has been tested on animals in a number of laboratories. The author's experience is summed up as follows: subcutaneous injection into rabbits causes characteristic blood changes—a rapid leucocytosis is followed shortly by a transitory leucopenia which reaches its acme at the end of 1½ to 2 hours and then gradually declines until in 24 hours the blood picture is normal. Leucopenia is accompanied throughout with lymphopenia. The parallel between this indirect method and direct *x*-raying is complete, although in the former the transitions are more abrupt and the phases much shorter. The x-serum contains two components which are antagonistic. The serum *per se* tends to cause leucocytosis, while the *x*-rays have the opposite tendency. The therapeutic possibilities of the combination have not yet been studied.

New Occupational Diseases Due to Calcium-Nitrogen.—Koelsch refers to the use of calcium nitride as a fertilizer which is being employed as a substitute for Chili saltpeter. It is prepared in the electric furnace, the nitrogen being supplied by the atmosphere. The commercial product contains 57 per cent. calcium cyanide, 21 per cent. caustic lime, 14 per cent. carbon, and 8 per cent. of impurities (silica, phosphoric acid, iron, etc.). In theory those who work in this fabrication could be poisoned in several ways, in addition to the dangers of caustic action and explosion, but such accidents are also preventable. As a matter of fact, it appears that only such workmen as use alcohol are attacked while at work. After ingestion of the latter the head is flushed, the limbs shiver as if with cold, there is dyspnea, and sense of pressure in the chest. Even a few swallows of beer suffice to bring on this disturbance. The upper portion of the body participates in the congestion which is also visible in the upper extremities, although the hands are cold. The respiration is 20-25, pulse 100-130, blood picture not changed. The sensorium is clear, the tremor is sometimes accompanied by jactitation, and there is a suggestion that these motor disturbances are psychogenetic, due to mental impression. The attacks last an hour or two and are followed by prostration. Tolerance does not develop, but after the Sunday rest the subjects even with alcohol ingestion develop no Monday attack. Working in dust is a contributory factor, and both it and alcohol seem necessary for the production of the attacks. The workers are not drinking men as a class and many are almost abstinent. Cyanimid is probably the industrial poison.

Death from the Use of a Quinine-Veronal Combina-

tion.—Erdt reports a death from the careless use of a synthetic or mixture in whooping cough. This preparation, marketed as a proprietary, contains 36 per cent. of veronal, and the single dose contains over one grain of the latter. The daily dose is, of course, left to the medical practitioner. The medicament comes in palatable chocolate tablets. A child aged 2½ years who was being treated for pertussis got possession of the container and ate nine tablets, equal to ten grains of veronal. It soon passed into a stupor, with cyanosis, and never rallied despite full antidotal procedure. Veronal crystals were recovered from the brain. The question arises, did the large quantity of quinine—nearly 20 grains—contribute to the death? The author believes that it was a contributory cause—since 18 grains of quinine have killed a two-year-old child. It is of interest to note that the child's father attributed death to washing out the stomach by the author.

Phenolsulphonephthalein in Testing the Renal Function—Hess concludes a serial article on this subject as follows: the Rowntree-Geraghty test excels all previously known methods in simplicity. No dietetic preliminaries are necessary and it can be made on subjects irrespective of the mental state. It can be made by the practitioner without recourse to a laboratory. It is an important accessory in the diagnosis of chronic interstitial nephritis, a condition often without any constant symptomatology, and it also has important prognostic significance. Since it parallels the results of examination for sodium chloride and urea it may replace these in routine work. In acute renal lesions it is less valuable when considered alone, and the curve often contradicts the clinical evidence. The test is no less valuable in surgical conditions in which one kidney is involved the urine being obtained by ureteral catheterization.

Surgical Observations from the Seat of War.—Kraske, the well-known surgeon of Freiburg, who is now at the front, writes that after the fighting on August 9-10, he was able to follow up the cases of about 600 wounded, who had been injured chiefly with small arm projectiles at a distance of some 400 to 600 meters. From four to five-sixths of these wounds were seated in the extremities. The left hand, from its exposed position, was often struck. There were a number of wounds of the left side of the skull, which indicated that the men had been lying prone with heads turned to the right, and that all had been struck by the same volley. The sorriest wounds were those in which the spine and cord were ultimately injured by bullets received while lying prone. Of thirty soldiers wounded in the thorax, many did not spit blood; and of twenty hit in the abdomen the majority of wounds had only transitory effects. In the wound dressing pavilions everything went ahead smoothly, but the transportation of the wounded was much impeded by the nocturnal fighting. The author was somewhat pessimistic at the outset and the good results have greatly exceeded his expectations. Simple occlusion of the wounds is doubtless responsible for the fact that as a rule inflammation, fever, pain, and systemic reaction have been absent.

Dietetic Treatment of Hyperacidity, Hypersecretion and Peptic Ulcer.—Strauss states that these conditions require practically the same diet. The first dietetic element for consideration is that which tends to inhibit hypersecretion. The classical researches of Pawlow have shown that the fats belong under this heading. The author at once tested this discovery in the clinic and learned that while egg-yolk, cream and butter were of use in this connection, fat bacon was unsuitable. Vegetable fats are well tolerated. Pawlow having shown that certain food articles increase secretion, such must be regarded as contraindicated, especially if they disagree with the patients. Here belong meat extractives, bouillon, coffee (even when deprived of caffein), carbonated drinks, sour wine, vinegar, mayonnaise, etc. A flesh free diet seems well borne in some cases, while in others it is enough to cut down the meat and order only that which is well cooked and tender and requires little mastication. Pawlow has proved that mastication causes a flow of gastric juice. The use of seasoning and relishes has the same result. For the same reasons the carbohydrate foods should also be tender and unseasoned. Soft bread, tender vegetables, cereal porridges, and plain puddings are recommended. If a peptic ulcer is present, with severe hemorrhage, the author advises exclusive rectal feeding, for which purpose he recommends cream, albumoses, milk, yolk of eggs, etc., with the addition of pancreatin. After hemorrhages has ceased, buccal feeding may be carefully resumed with bland foods having high caloric values. Cream, half milk and cream, yolks of eggs alone or beaten up with sugar, give a maximum of food value with a minimum of bulk. These fatty ingesta also antagonize the hypersecretion. After eight or ten days of absence of blood in the feces pigeon or chicken meat may be finely minced and passed through a sieve and then incorporated with flour porridge. Mashed potatoes and soft cheese stirred up with cream are also recommended. Other articles permissible at a later period, corresponding to the cicatrization of the ulcer, are calves' brains, roast pigeon, breast of chicken, brook trout, purees of vegetables with plenty of butter, dipped zwieback, apple sauce, etc.

Indicanemia and Uremia.—Tschertkoff states that in subjects, whether healthy or ill, whose kidneys function in the normal manner, neither urea nor indican are ever found in the serum. Whenever there is retention of urea we find indican in the latter. If the serum contains 1.5 per thousand of urea indican will surely be present. In chronic nephritis indicanemia has an unfavorable prognostic significance, showing a severe and irreparable alteration of the kidneys. In acute nephritis there is no such ominous significance attached to this find. In case as a result of special diet there is no marked retention of urea, indicanemia may still be present and be the sole evidence of renal insufficiency. The method of testing for indicanemia is as follows: the serum is freed from albumin with trichloracetic acid and then filtered. To 10 c.c. of filtrate add an equal amount of Obermayer's reagent. Indigo blue then forms. The filtrate is now agitated with 3 c.c. chloroform and the color compared with a standard scale. As is well known the mere addition of the acid to precipitate the albumin represents a qualitative test for indican provided the latter is present in large quantities, the mixture giving a color reaction which becomes more pronounced on standing in the sunshine.

Tuberculosis of the Mastoid.—E. D. Davis reports the case of a boy who had an abscess of the superficial parotid glands, and enlarged posterior auricular and upper deep cervical glands on the left side, left otorrhea, and left facial paralysis. The parotid abscess was opened and curetted, and the posterior auricular and cervical glands were removed. A radical mastoid operation was performed four months later, and more caseating cervical glands were removed. Finally, the area was opened up and a large sequestrum was removed. The disease was arrested.—*Proceedings of the Royal Society of Medicine.*

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

SUICIDE.

THE mortality statistics compiled by the Bureau of the Census of the United States gives the number of suicides occurring in the registration area as 9,622, or 16.2 per 100,000 population in 1911, and 9,656, or 16.0 per 100,000 in 1912. Deaths due to accident in 1911 amounted to 50,121, in 1912 to 49,775. A certain proportion of deaths due to accident may be attributed to suicide. Dr. E. J. Marsh, in his Report on the Mortality Records of the Mutual Life Insurance Company, gives the following figures:

DEATHS FROM VIOLENT CAUSES

	1843-1873	1874-1885	1886-1893	1894-1899
Suicides	991	248	299	383
Casualties	2346	507	685	797

Claims to the number of 162 with suicide acknowledged as a cause of death were submitted to the same company in 1913, of which 8 occurred during the first policy year. The number of cases, including those in the first year, would be higher if the suicides ascribed to accident could be ascertained.

The question of death by suicide is important to insurance companies, for the reason that applicants have undoubtedly secured insurance while premeditating self-inflicted death. The disordered mind leading up to such an act may be laid to the suicidal impulse of melancholia in nearly every case. The idea of self-destruction may be firmly controlled, or openly avowed and attempted. On the other hand, the intention may be cunningly hidden and the utmost ingenuity exercised in carrying out the plan. Certain individuals in the class last mentioned seek to provide for the subsequent maintenance of their dependents through the means of life insurance. The successful concealment of their intention to destroy their lives has led some insurance men to believe that a large proportion of suicides are responsible, rational and thoroughly conscious of what they are doing. It is an open question, however, whether completely sane persons will commit suicide, or that, while actuated by some strong, impelling distortion of the mind, they have controlled and concealed the predominating desire for self-destruction so successfully as to deceive all those about them. Moreover, it is difficult, in cases when suicide is suspected, to get the true cause of death for two reasons: that suicide of a member becomes a stigma upon the family and a frank admission might defeat the payment of the insurance.

It is a simple matter to produce proof that those contemplating suicide regard life insurance at times as a means for the future support of their families. Companies with no suicide clause in their applications have experienced from three to five times a greater percentage of deaths in the first policy years than in subsequent years. The deaths have not always been designated as suicidal, but the remarkable fact remains that the so-called accidental deaths have been much greater in the first year. Certain fraternal societies have reduced their mortality by adopting a suicide clause. Attention is called to this form of selection against the company in a paper by Rhodes read before the Actuarial Society of America which showed that proportionately five times as many suicides occurred under extended insurance as in the general business. The following cases may be cited as examples of this practice:

1. A supposedly wealthy and prosperous merchant recently secured policies for large amounts in several companies. As soon as he had these policies in his possession he applied for more insurance and continued in this course until he had about $800,000 in force. Very soon after the last transaction had been consummated he fell off a ferryboat under suspicious circumstances, refusing to take advantage of assistance proffered him from a nearby launch. Subsequent investigation revealed the fact that his financial affairs were embarrassed and that he was on the verge of business difficulties.

2. An application for $10,000 came to the writer's notice recently. There had been a suspicion of syphilis when this person made an application several years previously, and the application had been declined until satisfactory evidence was offered to the company. No reference to the syphilis appeared in the recent report, and the examination was made up in the Maine woods among strangers, where he had gone ostensibly to spend his vacation. Suspicions were aroused and issuance of the policy was refused until a complete investigation could be made, and in this way considerable delay ensued. Six weeks after the date of examination the applicant was killed by the accidental discharge of his revolver. He had been evidently under the impression that the policy was issued and in the possession of his representative, as he had informed his wife that he was insured.

Every company should have a suicide clause in its application by which the applicant agrees that the risk of death will not be covered by the policy if such death occurs by his own act, whether sane or insane, during a certain period, at least a year, following the date of issue. An individual premeditating suicide will seldom take insurance with the prospect of having to live a year before he can carry out his plan. Furthermore, as soon as he understands that there is a restriction in the application covering this point, he may even undergo a change in his mental process and conclude that he will be more valuable alive than dead to his family.

One large company advertised some years ago that its policies would be incontestable, without any exception, from the date of issue. In a few months a claim for $100,000 was presented to it, the applicant having committed suicide shortly after paying the first premium. This experience caused a prompt modification of the company's rule. Keen competition leads too often to excessive liberality in the way of removing restrictions of this kind, but conservative companies find that the interests of their policyholders are helped by resisting this temptation.

Insurance purchased by a person contemplating suicide constitutes a fraudulent proceeding, and there is no moral reason which justifies the payment of a death claim under such circumstances from the funds belonging to other policyholders who secured their policies in good faith. Nevertheless, the legislators of a certain State have placed a law upon its statute books which compels a company to produce proof that the applicant contemplated suicide at the time the policy was issued. This ridiculous law puts a burden of proof upon the company which it can only furnish by obtaining an affidavit from the applicant to the effect that he intends to commit suicide.

Examiners will assist their companies by carefully observing the mental condition of applicants and ascertaining whether there are any suspicious circumstances connected with the application.

Book Reviews.

TRAITÉ DE CYSTOSCOPIE ET D'URÉTROSCOPIE. Par le Dr. GEORGES LUYS, Ancien Interne des Hôpitaux de Paris, Ancien Assistant du Service des voies urinaires à l'Hôpital Lariboisière, Lauréat de la Faculté et de l'Académie de Médecine. Price 24 francs. Paris: Octave Doin et Fils, 1914.

IF experience had not shown that there is no such thing as finality in medical progress, we would be tempted to say that this treatise of Dr. Luys was the last word in endoscopy of the urinary tract. The author is one of the best known of Parisian urologists who has given us the results of more than fifteen years' practical experience in urethral and vesical endoscopy.

The first two chapters are devoted to urethroscopy, the others to cystoscopy. The first of these chapters, the third in the book, describes the various forms of cystoscope; the second the view of the bladder walls, normal and pathological, as seen through the cystoscope; in the third chapter cystoscopy by direct vision is described in detail; the next two contain an account of catheterism of the ureter and of the indications for treatment furnished by this procedure; the following chapter is devoted to the various operations upon the bladder wall performed through the cystoscope; and the final chapter deals with foreign bodies in the bladder and cystitis. The book is superbly illustrated with 217 figures in the text and 24 colored plates. It is a notable addition to the literature of urology.

TEN SEX TALKS TO BOYS (10 YEARS AND OLDER). By IRVING DAVID STEINHARDT, M.D. Author of "Ten Sex Talks to Girls" (14 years and older), Instructor in Clinical Surgery and Assistant Surgeon Cornell University Medical School; Assistant Pediatrist, Mount Sinai Hospital, O.P.D., New York City; Orthopedic Surgeon, New York Hospital, O.P.D., and Bronx Hospital and Dispensary; First Lieutenant, Medical Reserve Corps, U.S.A. With Twelve Illustrations. Philadelphia and London: J. B. Lippincott Company, 1914.

THERE may be valid differences of opinion as to the proper methods of teaching sex hygiene, but there can be no question that the growing boy should be told the fundamental facts about sex, that he should be impressed with the absolute compatibility of sexual purity with physical health, and that he should be warned against the dangers of illicit sexual indulgence. The average father hesitates to broach this subject with his son; the public school teacher is restrained by the conventional limitations of discussing sex hygiene with a large class of boys; and the family physician cannot as a rule spare the time to give a systematic and clear exposition of this subject to his young patient. The logical alternative is therefore the book that may be placed in the hands of the boy. This is the purpose of the book before us, and the book seems to answer the purpose very well.

PROCEEDINGS OF THE AMERICAN MEDICO-PSYCHOLOGICAL ASSOCIATION, at the Sixty-Ninth Annual Meeting held in Niagara Falls, Canada, June 10-13, 1913. Published by American Medico-Psychological Association, 1913.

TWENTY-SEVEN papers are embodied in this, the twentieth, volume of the transactions of the association. Among the more valuable articles of special interest to the general medical reader, may be mentioned: "The Genetic Concept in Psychiatry," by W. A. White; "Precipitating Mental Causes in Dementia Præcox," by A. Hoch; "The Diagnosis of the Higher Grades of Mental Defect," by W. E. Fernald; and "The Father Complex," by Helene J. C. Kuhlmann.

DAS ULCUS DUODENI. Von Dr. J. SCHRIJVER, Arzt für Magen- und Darmkrankheiten in Amsterdam. Paper; price 10 marks. Berlin: S. Karger, 1914.

THIS monograph is largely based upon a very scholarly analysis of the literature, most of which is of very recent origin, and every phase of the subject is adequately covered. The first chapter deals with the history of the recognition of duodenal ulcer, and the author admits that continental Europe has been far behind England and America, both in its recognition as a distinct clinical entity and in the development of the present operative technique, credit being given to Moynihan of Leeds and to the Mayos and Codman in America for having done the most valuable work along this line. Other chapters cover statistics as to relative and absolute frequency; etiology and pathogenesis; symptoms and diagnosis; differential diagnosis; explanation of phenomena, such as the character and time of appearance of pain, etc.; course and treatment; while the final chapter summarizes the author's personal experience of 95 cases in the last three years, 13 women and 82 men, in whom he had made the diagnosis of ulcer of the duodenum, together with the history and operative findings in a number of his cases. The work is an excellent epitome of the subject.

FEEBLEMINDEDNESS—ITS CAUSES AND CONSEQUENCES. By HENRY HERBERT GODDARD, Ph.D., Director of the Research Laboratory of the Training School at Vineland, N. J., for Feebleminded Girls and Boys. Price $4.00 net. New York: The Macmillan Company, 1914.

THIS book constitutes one of the most important studies in feeblemindedness that has been made within recent years. It is based upon the large amount of material in the Training School at Vineland, N. J., for Feebleminded Boys and Girls. An investigation was made of 327 cases in the institution, and field trips were made to the homes of the inmates or to the localities in which their families had lived and all the available data pertaining to their antecedents were gathered and recorded. The book opens with a discussion of the social problems that must be considered in connection with feeblemindedness. Emphasis is placed upon the conception of intelligence as a relative quantity: individuals who may be normal in a simple environment may be unable to get along in a more complex social group. The greater part of the book consists of detailed case histories with pedigree charts of 327 families, and with 121 portraits of children. These data are then analyzed with the view of determining the causes of feeblemindedness. The overwhelming influence of heredity is pointed out. Other factors such as accidents before or after birth, meningitis, etc., are discussed. The family charts are summarized and an analysis is made of the conditions or diseases accompanying feeblemindedness, such as paralysis, epilepsy, insanity or syphilis in the parents, tuberculosis, sexual immorality, illegitimacy, criminality, consanguinity, etc. The author discusses the Mendelian law in relation to feeblemindedness, and finds that although before he studied his data he doubted the applicability of this law to his cases, nevertheless he is led to conclude that feeblemindedness is transmitted as a unit character. In the final two chapters there are presented the conclusions of this most important study. The eugenic program is outlined and the relative merits of colonization and sterilization are discussed. The points brought out in the final analysis are clearly summarized in the following words: "First: the mere recognition that there is a problem of the feebleminded will go a long way toward its solution. Second: a large part of the mental defectives who cannot be segregated may be reasonably and safely cared for in their homes, when we learn to recognize them for what they are, children in intelligence, though men and women in body. Third: We must increase our efforts to segregate as many as possible, because for a long time to come there will be a larger number who need colonization than we can possibly care for. Fourth: We must have sterilization wisely and carefully practised for the solution of many individual problems that are not reached by any other method. In conclusion we believe that we have demonstrated that feeblemindedness is sufficiently prevalent to arouse the interest and attract the attention of all thoughtful people who are interested in social welfare; that it is mostly hereditary; that it underlies all our social problems; that because of these facts it is worthy the attention of our most thoughtful statesmen and social leaders; that much of the time and money and energy now devoted to other things may be more wisely spent in investigating the problem of feeblemindedness; and that since feeblemindedness is in all probability transmitted in accordance with the Mendelian Law of heredity, the way is open for eugenic procedure which shall mean much for the future welfare of the race." These sentences present the problem of feeblemindedness in a clear light as one of the most important with which society has to deal. Dr. Goddard has performed an invaluable service in writing this book, which may be recommended without reserve to physicians, educators, legislators, and all others who are interested in social welfare.

Blood Pressure: Its Clinical Applications. By George W. Norris, A.B., M.D., Assistant Professor of Medicine in the University of Pennsylvania; Visiting Physician to the Pennsylvania Hospital; Assistant Visiting Physician to the University Hospital; Fellow of the College of Physicians of Philadelphia. Illustrated, with 98 engravings and 1 colored plate. Cloth, $3.00, net. Philadelphia and New York: Lea & Febiger, 1914.

In these days when so much is said and written of blood pressure one wonders how we got along as well as we did a few years back when all we had to guide us as to the state of the circulation was the pulse. As a matter of fact, however, the significance of blood pressure is by no means fully understood as yet, and whether high pressure is a cause or a consequence of certain morbid states is still a matter of investigation. There is no lack of literature on the subject, but in the fluid state of our knowledge regarding it this is to be welcomed, for each book as it appears, if of any value whatever, is sure to have something new and much that is old expressed in a new way. The latest contribution to this literature is the work before us. In it Dr. Norris has presented the subject in condensed and practical form, and as definitely as the present state of our knowledge permits.

After a discussion of blood pressure—what it is and why it is, and the present methods of estimating it, the book takes up the question of blood pressure in relation to acute and chronic infectious diseases, cardiac and cardiovascular troubles, arteriosclerosis, nephritis, metabolism, surgery, gynecology, and ophthalmalogy, a final chapter, and a very good one, being devoted to treatment so far as this can be devoted to a condition which is becoming more and more to be regarded as a symptom rather than a morbid entity.

Hygienisches Practikum, Ein Taschenbuch für Studierende, Ärzte und Kreisarztkadidaten. Von Dr. med. Paul Uhlenhuth, Geh. Reg.-Rat und ordentl. Professor der Hygiene an der Universität Strassburg, i. E. und Dr. med. Hermann Dold, Privatdozent der Hygiene an der Universität Strassburg, i. E. mit 1 Tafel und 89 Abbildungen. Price, $1.25. Berlin: Verlag von Urban & Schwarzenberg, 1914.

This book contains a description of the subject matter offered in the hygienic course at the university of Strassburg. The book is not a substitute for the larger works on this subject and only attempts to give a slight stimulus for the practical application of most of the methods of examining soil, water, food products, clothing, air and light.

Ambidexterity and Mental Culture. By H. Macnaughton-Jones, M.D., M. CH., Q.U.I. (Hon. Cau.) F.R.C.S.I. and ED., Ex-University Professor, Queen's University, Ireland; Honorary Member of the Societies of Obstetrics and Gynecology, Leipzig, Munich and Rome; Ex-President of the Obstetrical and Gynecological Section of the Royal Society of Medicine, The British Gynecological Society, and the Irish Medical Schools and Graduates' Association. Price $.75 net. New York: Rebman Company, 1914.

An interesting and convincing brief for ambidexterity is presented in this volume. The physiological and psychological bases of ambidexterity are discussed. Of the various selective influences that have brought about the predominance in the use of the right hand, environment, circumstance, education, and heredity are the main factors. The influence of asymmetry or of so-called mental polarization is also a potent factor. The author points out the important relationship between the speech and writing centers and the centers which control the movements of the upper limb on the opposite side of the body. Early education of both hands tends to develop the functional powers of the speech and writing centers on both sides of the brain, and inasmuch as these centers tend to dominate the entire intellectual field, the conclusion is drawn that ambidexterity makes for greater mental development, *i.e.* "greater facility of expression in language, greater retentiveness, more rapid conversion of thought into audible and invisible speech, quicker appreciation of impressions, as of size, form, weight, and color, and the fixing of these on the tablets of memory for future use." Ambidexterity is taught in the Japanese schools and is practised in all their arts. The author points out a subtle relationship between ambidexterity during its acquisition by the developing mind and the molding of character. Among the great artists who were ambidextrous are mentioned Leonardo da Vinci, Hans Holbein, and Landseer. The author would add to the Montessori method of education the cultivation of ambidexterity. Among the practical benefits of ambidexterity are the advantages of the use of the left hand when the left speech and motor centers are affected by disease; and the obvious advantages in self-preservation, particularly in averting accident.

A Treatise on the Mineral Waters of Vichy for the use of Practitioners. By Charles Cotar, (M.D., Paris), Consulting physician at Vichy with a foreword by Vaughan Harley, M.D., Professor of Pathological Chemistry, University College, London. Price, 4 shillings, net. London: H. K. Lewis, 1913.

The waters of Carlsbad and other German Spas, as a medical means of treatment, are thoroughly appreciated by our British confreres. It is only by reading a book like the admirable one brought forward by Dr. Cotar that one can readily realize the great value of a systematic course of mineral water treatment as carried out at Vichy, in the various medical cases where it is applicable. The book deals with the subject in a truly scientific way and a most valuable chapter is appended showing the reasons why mineral waters are, from a physiological point of view, a proper method of treatment. The value to medical men lies in the complete résumé of the whole treatment of disease by Vichy waters in particular, as well as by mineral waters in general.

Recreations of a Physician. By A. Stuart M. Chisholm, Author of "The Independence of Chile." Price $2. New York and London: G. P. Putnam's Sons, 1914.

With rare literary skill the author has written a volume that cannot fail to interest and delight the physician who would seek relief from the monotony of his scientific books by an occasional excursion into the byways of belles-lettres. The book consists of the following essays: Specialization; Physicians As Men of Letters; Banquo; The Symbolism of Names; Royal Authors; The Inherent Spirit of Medicine; On Some Translations of Horace; Some Features of the Science of Medicine in the Seventeenth Century; The Picaro in Fiction; and On the Prevention of Disease. In the essay on specialization the author discusses the narrowing and blighting influence of the latter and describes the many ways in which the physician may counteract this influence in his leisure hours. In "Physicians As Men of Letters" there are presented charming word-portraits of Keats, Smollett, Goldsmith, Sir Samuel Garth, Akenside, Rabelais, Sir Thomas Brown, Cowley, Arbuthnot, and Oliver Wendell Holmes. Among the other medical men who transferred their allegiance from Æsculapius to the fine arts are mentioned Sir Samuel Smiles, Marat, Lessing, Schiller, the elder Scaliger, Christopher Wren, Charles Lever, the philosopher Locke, and George Crabbe. In "Banquo" the author delineates one of the "stars of the second magnitude" among Shakespeare's characterizations. "On the Symbolism of Names" is a scholarly and witty disquisition on the psychology of this subject.

A Manual of Diseases of the Nose and Throat. By C. G. Coakley, A.M., M.D., Professor of Laryngology in the College of Physicians and Surgeons, Columbia University; Consulting Laryngologist to the Sea View Hospital, to the New York Infirmary for Women and Children, and to the New York Board of Health; Consulting Otologist to Minturn Hospital; Fellow of the American Laryngological Association; Fellow of the American Otological Association; Fellow of the New York Academy of Medicine; Member of the Medical Society of the County of New York, of the State of New York, and of the American Medical Association, etc., etc. Fifth Edition, Revised and Enlarged. Illustrated with 139 Engravings and 7 Colored Plates. Price $2.75. New York and Philadelphia: Lea & Febiger, 1914.

This work admirably serves the needs of the student and the practitioner. Emphasis is placed, as in former editions, upon the practical aspects of the study of diseases of the nose and throat, *i.e.* upon examination, diagnosis and treatment. In presenting the treatment of any condition the author describes in detail the method which he considers the best. A special chapter on therapeutics has been added. The book is profusely illustrated, the series of seven colored plates particularly being admirable.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held October 1, 1914.

THE PRESIDENT, DR. WILLIAM M. POLK, IN THE CHAIR.

Wesley M. Carpenter Lecture.—Dr. WALTER B. CANNON of Boston, George Higginson Professor of Physiology, Harvard University, delivered this lecture, choosing as his subject "The Physiological Equivalent of War." He stated that his original intention had been to present an account of some of the recent investigations which they had been conducting in the Harvard Physiological Laboratory, but that the events of the past summer had suggested a practical application of their results pertinent to present interest. He pointed out that the doctrine of human development from subhuman antecedents had done much to unravel the complex nature of man both in solving the puzzle of the details and conditions of anatomical structure and in accounting for functional peculiarities. In no respect, however, had biology contributed more to clarify our views than in throwing light on the ways of human behavior. The comparative study of the behavior of men and lower animals was making it clear that the springs of action were to be found in the influence of certain emotions which expressed themselves in characteristic instinctive acts. Dr. Cannon then described the combinations, anger-emotion with pugnacity-instinct, and fear-emotion with fight-instinct, and said that the major emotions, anger and fear, were also peculiar in being accompanied by bodily changes which were probably much more profound than those attending any other affective states. It was with these changes that their studies were concerned. The parts of the organism which were peculiarly called into action in emotional excitement were glands and the smooth muscle of viscera. The pouring out of tears, the "cold sweat," the dilation of pupils, the erection of hairs, the pallor from contracted blood vessels were well known changes from the routine of life in organs not subject to voluntary control. That there were other important visceral responses in strong emotions suggested itself to the speaker while he was watching the movements of the stomach and intestines with the *x*-ray, during 1896-97, when he noted that any sign of rage or anxiety or distress would be accompanied by total cessation of these movements. It had since been shown that the secretion of every one of the digestive glands, as well as the flow of bile, was stopped under great excitement. A rather remarkable feature of such inhibition of secretory activity was its prolongation. The portion of the nervous organization of the body by which these emotional alterations were directly wrought was the so-called sympathetic division of the viesceral system. Subject to the same impulses that brought about these changes were the adrenal glands. When these glands were stimulated through their nerve supply they poured into the blood stream a substance, adrenin, which had remarkable properties in relation to the organs to which the sympathetic fibers were distributed. It was capable of evoking in these organs all the changes that were evoked by the sympathetic nerve impulses themselves. It seemed possible, therefore, that the continuance of emotional disturbance in the body long after the occasion for it had disappeared might be due to adrenal secretion. In that case it might be true that the visceral changes attending excitement would be produced initially by the nervous discharges along sympathetic fibers, that these impulses would also arouse secretion of the adrenal glands, and that this secretion circulating in the blood would continue by chemical influence the disturbances which were nervously initiated. Such was the theory which underlay their investigations. The speaker then recounted the experiments with the blood of "quiet" and "excited" animals from which they drew the conclusion that the inhibitory influence of excited blood was in fact due to adrenal secretion, and that therefore the adrenal glands were brought into action under strong emotions. This conclusion had been confirmed both in this country and in England. For many years it had been recognized that the injection of adrenin brought about a liberation of sugar from the liver and thereby might increase the sugar content of the blood to such an extent that it flowed over the dam in the kidneys and resulted in glycosuria. It altered the distribution of the blood in the body, depleting abdominal viscera, and flushing the heart, the lungs, the central nervous system and the limbs. It seemed to act as an antidote for muscular fatigue. The question thus at once arose after the above investigation "Does the adrenal secretion poured out in emotional excitement likewise produce or cooperate in producing these same effects?" They had found that from emotional excitement alone a greater or less degree of glycosuria resulted. The glycosuria failed to appear if the adrenal glands were removed. These observations harmonized with the experimental discoveries that stimulation of the nerves supplying both the liver and the adrenal glands would increase blood sugar at the expense of hepatic stores, but that this failed to occur if the adrenal glands were not present. The establishment of glycosuria, therefore, implied help from the adrenal secretion. Evidence reported both from this country and abroad during the past two years tended to emphasize the importance of emotional conditions for the increase of blood sugar, and the expression "emotional glycosuria" was becoming recognized as descriptive of an important bodily reaction. Adrenin, besides checking the function of the digestive organs, drove out from these organs the excess of blood no longer needed there and forced it the more rapidly through the heart, the lungs, the central nervous system and the limbs, and it was significant that all these organs were intimately cooperative in vigorous muscular exertion. Muscular work was favored by the effects of adrenin not only through the altered distribution of blood, but also in a more direct manner. As a muscle was fatigued it became much less irritable. If instead of waiting for a natural recovery from fatigue a small dose of adrenin was injected into a vein, or if through their nerves the adrenal glands were stimulated to secrete, full restoration of the fatigued muscle had been observed to take place within a few minutes. These remarkable changes which occurred in the presence of fear and anger were not in the slightest degree subject to voluntary control, and hence it was pertinent to inquire as to their utility in either preserving the welfare of the organism or safeguarding it against injury. The speaker then proceeded to show that underlying both the fear-flight and the anger-attack complexes was the instinct of self-preservation—in the weak developing into fear and running, and in the strong into hostility and aggression. Under circumstances demanding either flight or combat there would be a use of the great muscular masses in the body in supreme, and perhaps prolonged, effort. The sugar which, with the aid of adrenal secretion, was liberated from storage in the liver at times of great excitement would consequently be of immediate benefit to the organism in the strenuous muscular efforts involved in running, confiict, or struggle. The adrenal secretion poured out under excitement would place the muscles of the body unqualifiedly at the disposal of the nervous system. At the same time the difficulty which nerve impulses might have in calling into action the muscles would be practically abolished; this, together with the sugar newly swept into the circulation, would provide the mechanism most efficient for putting forth the utmost efforts. Quite in harmony with this interpretation were the vascular changes wrought by adrenin in cooperation with sympathetic discharges, which gave to the parts called on for action a bounteous supply of blood. The speaker also considered the part played by the adaptive reactions, forced respiration and "sweating," and showed that all of these physiological changes were directly serviceable in making the organism more effective in the struggle which fear or rage might involve.

Dr. Cannon stated that it was commonly recognized that the major emotions had an energizing influence, and cited instances of extraordinary feats accomplished under the impulse of fear. It was highly significant that in periods of great excitement there was no infrequent testimony to a sense of overwhelming strength that lifted a person to a new high level of confidence in his ability. He described the intense satisfaction in these moments of supreme elation and the fascination found in critical dangers of adventure. For these reasons vigorous men went forth to seek danger and to run large chances of injury. In the major sports the conditions were favorable for the development of intense emotional excitement and for the exhibition of great feats of strength and endurance. Football was instanced as an example where all the pomp and circumstance attendant on a great contest made every member of the team to realize vividly his responsibility

for the supreme, all-important result—victory for his group. Last fall twenty-five members of the Harvard University football squad were examined directly after the game with Yale, and in twelve of them glycosuria was found. Five of the twelve were substitutes who did not have a chance to play, and it was clear that the bodily responses in these athletes were wholly analogous to those previously found as accompaniments of strong emotion in the lower animals. Furthermore, the changes in the men were quite as directly adapted to the powerful muscular efforts which their game demanded, as were the similar changes which occurred in the lower animals which were adapted to their occasional fierce struggles for existence. What was true of football was true to a lesser degree of such sports as running, rowing, hurdling.

Dr. Cannon traced the analogy between fear and rage as exhibited in animals in their struggle for existence to those emotions and instincts in human beings which sometimes seize upon individuals in groups and spread like wild-fire into larger and larger aggregations of men, until vast populations were shouting and clamoring for war. The strength of the fighting instinct in man had been one of the main arguments of the militarists. They pointed to the historical fact that even among highly civilized peoples scarcely a decade passed without a kindling of the war spirit which exploded in actual battle. War, they said, was therefore, inevitable. They argued that the warlike qualities were essential to human welfare, and that they must be occasionally exercised lest the people sink into self-indulgence and become weakened and softened. War disciplined character, taught men to be brave and patient, promoted virility and hardihood and renewed a true order of life's values. These arguments were nowadays strongly contested. War had become too horrible; it was conducted on too stupendous a scale of carnage and expenditure; it interfered too greatly with consecrated efforts to benefit all mankind by discovery and invention; it involved too much suffering among peoples not directly concerned in the conflict; it was too vastly at variance with the methods of fair dealing that had been established between man and man; the human family had become too closely knit to allow some of its members to bring upon themselves and all the rest poverty and distress and a long heritage of bitter hatred and resolution to seek revenge. There was, then, a war against war, a willingness to fight against monstrous carnage and destruction that grew in intensity with every war that was waged. The situation thus developed revealed clearly the importance of preserving the martial virtues. What was needed was not a suppression of these capacities to feel and act, but their diversion into other channels where they might have satisfactory expression. As James wrote "We must make new energies and new hardihoods continue the manliness to which the military mind so faithfully clings." Martial virtues must be the enduring cement; intrepidity, contempt of softness, surrender of private interest, obedience to command, must still remain the rock upon which states are built." James suggested what he called "a moral substitute for war," which should consist of such required service in the hard and difficult occupations as would take the childishness and superciliousness out of our youth and give them soberer ideas and healthier sympathies for their fellowmen. He conceived that by proper direction of its education a people should become as proud of the attainment by the nation of superiority in any ideal respect as it would be if the nation were victorious in war. "Strenuous honor and disinterestedness abounded elsewhere. Priests and medical men were in a fashion educated to it, and we should all feel some degree of it imperative if we were conscious of our work as an obligatory service to the state. We should be owned as are the soldiers by the army and our pride would rise accordingly. We could be poor, then, without humiliation, as army officers now are. The only thing needed henceforth is to inflame the civic temper as past history has inflamed the military temper."

In the evidence offered earlier, Dr. Cannon believed, lay the alternative to the claims of the militarists. As James offered a moral substitute so coordinately he offered a physiological substitute for war. It was shown that when as a result of intense excitement the body went onto a war footing a number of fundamental physiological changes suddenly occurred, all of them adapted to the putting forth of supreme muscular and nervous power. That was what primitive battle consisted of, through countless myriads of generations. A comparison of such contests with modern warfare showed that war under modern conditions of the dull grind of drill, the monotonous regularity of subservience, the substitution everywhere of mechanism for muscle, and sometimes even the attack of an enemy beyond the range of vision failed to satisfy the lust of combat. On the other hand, it was a demonstrable fact that strenuous athletic rivalries presented, better than modern warfare, the conditions for which the body spontaneously prepared when the passion for fighting prevailed. In the competitive sports the elemental factors were retained, man was again pitted against man, and all the resources of the body were summoned in the eager struggle for victory. The evidence was wholly clear that under such circumstances the same physiological alterations occurred that occurred in anticipation of mortal combat. For what might be called a physiological equivalent of war Dr. Cannon, therefore, suggested the promotion of great international athletic contests, such as the Olympic games, which would do for our young men much that was now claimed as peculiar to the values of military discipline. Such a substitution of athletic rivalries for battle had been successfully applied among several of the fiercest Philippine tribes. There were other aspects of international games which strongly commended them as an alternative to the pursuit of military discipline. The high standards of honor and fairness in sport; its unfailing revelation of excellence without distinction of class, wealth, race, or color; the ease with which it became an expression of the natural feelings of patriotism; the respect which victory and pluckily borne defeat inspired in competitors and spectators alike; the extension of acquaintance and understanding which followed from friendly and magnanimous rivalry among strong men.

SECTION ON PEDIATRICS.

Stated Meeting, Held May 14, 1914.

Dr. WILLIAM P. NORTHRUP IN THE CHAIR.

Pyloric Spasm.—Dr. MARK S. REUBEN presented this patient, the youngest of three children. The first child died of inanition at the age of three months, having presented the same symptoms as the patient except that they were more severe and persisted until death. The child probably had a hypertrophic stenosis of the pylorus. The second child was five years of age and had always been well. The patient came under observation at the age of eleven weeks. When six weeks of age he began to vomit, the vomiting being projectile in character and taking place from five to ten minutes after nursing. There was steady loss in weight and obstinate constipation. A pyloric tumor could be felt and the peristaltic waves were perceptible. The diagnosis of pyloric obstruction was made. After three or four attempts Dr. Hess succeeded in passing the duodenal tube, thus ruling out pyloric stenosis, and making the diagnosis of pyloric spasm possible. There were four to five ounces retention three hours after nursing. The infant was kept on the breast alone for four weeks, the intervals between feedings being three hours. The child continued to lose weight and all the symptoms persisted. The combined acidity at this time was from 115 to 85 degrees, and there was no free hydrochloric acid. By weighing the infant before and after feeding it was found that he was getting from four to five ounces at a feeding and examination of the mother's milk showed it to be of good quality. Complementary feeding was instituted after four weeks. Two grains of sodium citrate were added to every ounce of milk. Immediately the child began to gain in weight and all the symptoms subsided. A pyloric tumor could no longer be felt and the peristaltic waves were no longer visible. The retention in the stomach gradually diminished. The combined acidity continued to be from 100 to 85, and a trace of free hydrochloric acid was present. The points of interest in this case were: (1) There were two cases of pyloric obstruction in one family, both males; in one case the obstruction was of high grade and led to a fatal termination, while in the other it was mild and led to speedy recovery. These cases lent proof to the statement of Dr. Holt, who was of the opinion that in all these cases there was a real stenosis varying in degree in different cases. (2) The almost immediate improvement when complementary feeding was instituted.

(3) The disappearance of pyloric tumor when the child began to gain. (4) The persistence of the high acidity even when the infant was doing well, proving that the spasm was not due to high acidity. (5) An *x*-ray of the stomach taken since the child was doing well still showed much delayed transmission of food. Therefore too much reliance should not be placed on the *x*-ray findings in these cases but rather more on the clinical phase.

Congenital Hypertrophy of the Left Half of the Face in a boy Seven and One-Half Years of Age.—Dr. SARA WELT-KAKELS presented this patient, whose family history showed no consanguinity, no lues, and no tuberculosis. A sister two and one-half years of age was perfectly healthy. The patient was born at the end of a normal pregnancy. The deformity was noticed at birth. There was nothing abnormal in dentition or in the time of walking or talking. The patient has had whooping cough and measles, and occasionally sore throat, but otherwise has enjoyed good health. The facial hemihypertrophy had retained its proportions in relation to the right half of the face. At present the enlargement of the left half of the face was mainly in the lower two-thirds, not only the soft parts but the bones as well were involved. The enlargement of the cheek was most prominent; the upper and lower lips were much hypertrophied; the left angle of the mouth was drawn downward; the left nasolabial fold was effaced. The left half of the nose was large, but there was no hypertrichosis or coarseness of the hair. In the malar region there was a small elangiectasia about a quarter of an inch in diameter surrounded by a small pigmented area. The action of the facial muscles was somewhat interfered with by the hypertrophy, but the boy could frown, laugh, and whistle. There was a slight diminution in the response to the faradic current, but no disturbance of the sensibility of the special senses. There was sometimes salivation, seemingly from the left side. The mouth was mostly kept open, the left half projecting and the upper lip forming an ectropon. The appearance of the tongue was very conspicuous. It had been said that this organ participated only in the congenital and not in the acquired form of facial hemihypertrophy. The point of the protruded tongue deviated to the right. The left half of the tongue was four or five times the size of the right. The left half of the hard and soft palate, the left tonsil, and submaxillary gland were involved. On the inner surface of the left cheek were a few small tumors about the size of a pea. Like the cheek they gave the impression of lipomatous growth. The left upper jaw was much enlarged and thickened, especially in the alveolar portions, and the teeth were irregularly inserted. The left half of the lower jaw was also involved but to a slighter degree. The boy was otherwise fairly well developed and showed no other abnormalities. He had a good intellect.

Dr. HENRY M. STARK said that in view of the fact that the lipomatous tissue of the cheek and upper and lower lips were the seat of the maximum "giant" growth, it had seemed to him that the enormous hypertrophy was not without surgical possibilities, even though it was quite possible that subsequently, and after a long while, the initial results might have to be revised. That was, that even though some of the excess tissue should now be removed, as it was proposed soon to do, there might be in time a regrowth of this tissue, again calling for its plastic removal. It was proposed to remove in several sittings enough of the excess tissue to give for the present, and it is to be hoped for a long time, a good cosmetic effect. As Dr. Kakels had said, all the histologi-elements in the region were involved in the giant growth. Should the bony structure at any time take on extraordinary growth, any attempt at plastic correction would then be out of question.

The Roentgen Ray as a Diagnostic Help to the Pediatrist.—Dr. L. E. LA FETRA presented this paper. He stated that the value of the *x*-ray as an aid in diagnosis in surgical conditions that involved the bones and joints, and in abdominal and chest conditions in the adult were too well known to require comment. In children the value of the *x*-ray in fractures, dislocations, rachitis, chondrodystrophy, tuberculosis, and syphilis was thoroughly appreciated, but there were also medical conditions in which the *x*-ray made an early and positive diagnosis, which would not be possible otherwise and it was these that the essayist considered, confining himself to such conditions as had come under his personal observation. Enlargement of the thymus gland had been found several times simply as an incident of thoracic examination when there had been no cause to suspect it. The frequent fallacy of percussion in the diagnosis of enlarged thymus had been demonstrated by the *x*-ray. In several instances plates taken for the purpose of showing the extent of an empyema had revealed foreign bodies in the bronchus as the cause of the broncho-pneumonic abscess in empyema. This had directed the treatment along proper lines and proved life-saving. For the detection of abscess of the lung, the extent of empyema, and also in the early diagnosis of pneumonia, the *x*-ray had proved of the greatest value. In pneumonia where it had been impossible by the physical signs to localize the disease, the *x*-ray had shown with great delicacy the beginning of consolidation. Pneumothorax was another condition beautifully shown by the *x*-ray. The *x*-ray and the von Pirquet test had removed the diagnosis of miliary tuberculosis from a region of suspicion to one of certainty. Often unsuspected cavities had been found, usually near the apex and in very young children. The *x*-ray was of service in diagnosing pericardial effusion from cardiac enlargement, and also in showing the best place for puncture of the pericardium. It also enabled one to follow with greater accuracy the increase or diminution in the amount of pericardial fluid. The *x*-ray furthermore gave valuable information in regard to stenosis of the esophagus, especially where this was spasmodic or cicatricial, and it might be of value in pyloric stenosis, though here it was not at all essential and was sometimes misleading. For the diagnosis of early bone syphilis and for the differential diagnosis of syphilis from scurvy and of syphilitic bone disease from tuberculous bone disease, particularly in cases of dactylitis or epiphysitis, the *x*-ray was of the greatest value.

An Application of the Roentgen Ray to Infant Feeding.—Dr. CHARLES HENDEE SMITH presented this communication. He pointed out that the teaching of doctors and nurses for many years had been that the child must be kept at the breast or bottle for twenty minutes, must then be held in a perfectly horizontal position, and be put to sleep at once without change of position. Many mothers did not follow this plan, but allowed the child to take a longer or shorter time for nursing and then held him up against the shoulder after feeding, or prone across the knees or trotted him up and down in a sitting posture; finally, after an interval putting him to sleep. One of these plans must be more desirable than the other. The posture of the child after feeding was of importance because of its relation to vomiting, colic, sleep, and general health. Radiography had shown the fallacy of the old idea that the stomach was vertical in infancy. The cardiac orifice was held firmly to the posterior abdominal wall. The fundus lay in the left paravertebral groove, on the diaphragm, spleen, tail of the pancreas, kidney and mesocolon, reaching a plane considerably posterior to the cardia; since the vertebræ projected forward some distance into the abdominal cavity the pyloric end of the stomach was also pushed forward by the vertebræ, the head of the pancreas and the duodenum, and lay in contact with the anterior abdominal wall and liver anteriorly. The pyloric opening was directed backward to the duodenum, but lay in a somewhat more anterior plane than the cardia. There was therefore an obliquity of the long axis of the stomach from behind forward and to the right as well as from above downward and to the right. The cardiac opening was nearer the most posterior plane of the stomach than it was to the most anterior. The second factor in regard to posture was that there was a certain amount of gas in the stomach of every individual. Practically every radiograph taken in the erect position showed a bubble of gas in the fundus end of the stomach. In the prone position it was not possible to estimate the amount of gas present. The gas in the stomach might be derived from swallowed air, gastric fermentation, and intestinal gas. Swallowed air accounted for the gas in the stomach in the majority of cases. If the child was held in the horizontal position the liquid gravitated to the posterior part of the stomach, and that was the fundus, and forced the gas to the anterior part and to the right end of the body of the stomach and pyloric antrum. Hence it followed that the cardiac orifice situated well back against the vertebral column would be covered by the liquid and the gas could not escape into the esophagus. It could only escape through the pylorus if at all. If the amount of food plus gas was enough to distend the stomach either food or gas must be forced out through the pylorus, or

food must be regurgitated through the esophagus until the tension was relieved on the stomach wall. When the child was held upright the liquid gravitated at once to the most dependent part of the stomach, displacing the gas to the highest point, making it possible for it to escape through the esophagus. Dr. Smith exhibited *x*-ray plates illustrating these points and drew the following conclusions: (1) Regurgitation, colic, and indigestion depended not only on the food but on the manner in which it was given and the posture of the child between feedings. (2) The food must be of proper composition and proper amount. It should be given at as long intervals as possible, depending on the gastric capacity and the total amount of food required per day. (3) A feeding should not be taken too slowly, five to ten minutes being long enough and fifteen minutes being the maximum time. (4) The child should be held upright before feeding to get rid of any gas in the stomach. If air was swallowed in large quantities it was often necessary to interrupt the feeding one or more times holding the child erect until the air had been expelled. Immediately after feeding the child should be held upright against the mother's shoulder and given the opportunity to eructate gas. (5) The child should be placed in bed preferably in the prone position with the head of the bed somewhat elevated. This routine might be followed with every child even though he did not regurgitate. Habitual tongue suckers had to be held up sometimes between feedings.

The Roentgen Ray and Pneumonia.—Dr. HOWARD H. MASON made this presentation, a lantern slide exhibit showing what the *x*-ray revealed in pneumonia. A series of slides demonstrated the correlation between the beginning of the physical signs of pneumonia with the appearance of the shadow showing the beginning of consolidation. Other plates showed that with the disappearance of the physical signs of pneumonia the shadow of consolidation cleared up. The *x*-ray had shown that when a lung cleared it seemed to clear equally all over and not from within outward or from without inward. Quite a change in the shadow was frequently noted within twenty-four hours. In all the early cases before the lung consolidated there was just dullness, but when consolidation extended to the larger bronchi one got all the signs of pneumonia, bronchial breathing, râles, etc. Still other slides showed the differences between the shadow of bronchial pneumonia and that of lobar pneumonia.

Dr. WILLIAM P. NORTHRUP asked Dr. Mason whether in the old-fashioned so-called central pneumonia it was an undiscovered marginal lobar pneumonia that one had.

Dr. MASON replied that it was like the case shown, usually in the region of the scapula and difficult to make out. There were breath sounds, a few râles, and dullness, but no bronchial breathing.

Dr. NORTHRUP said he was reminded of a case in his practice in which the child had a high temperature and slight stupor; in fact, all the rational signs, but no local physical signs of pneumonia. The patient recovered by crisis and went on living. Competent men had seen the case in consultation with him and they all felt chagrined that they could find no local signs of the disease.

Dr. WARD BRYANT HOAG asked why there was so much consolidation shown in lobar pneumonia, while in typical pneumonia with high temperature, rapid respiration, and bronchial breathing, the *x*-ray did not show such a marked shadow. In one case that came under his observation in which there were no physical signs on the sixth day Dr. Kerley was called in consultation and he could make out no local physical signs. On the seventh day they did not take the sounds, but on the eighth day the child began to show physical signs and the first attempt to take the sounds with the stethoscope revealed the lesion, and on that same night the child's temperature fell from 106° to 96° F.

Dr. S. I. HIRSCH said that in regard to the difference between bronchial and lobar pneumonia he did not agree entirely with Dr. Mason. It was the general consensus of opinion that the pulmonary markings were due in lobar pneumonia to the blood vessels passing from the hilum to the periphery; the veins, arteries, and capillaries all took part, and the density was due to the congestion of the blood vessels. The bronchi in the *x*-ray picture seldom showed except at the hilum and then but slightly in contrast to the thick shadow at the base. In pneumonia there were small spots showing the infiltration in the air vesicles. In all bronchial pneumonia there was a tendency to confluence and these small spots tended to coalesce. In lobar pneumonia there was an even density during hepatization and this served to differentiate the two forms of pneumonia.

Dr. NORTHRUP said it was most illuminating to see what had been unearthed by the *x*-ray. In the Presbyterian Hospital Dr. Mason had had a case of tuberculous meningitis in which the lungs showed no signs whatever of tuberculosis and yet the *x*-ray showed the lungs studded with miliary tubercles. The *x*-ray had certainly brought to them a new and valuable aid in dealing with children's diseases. In this case just referred to, at autopsy all the areas that the *x*-ray had indicated as affected were found to be involved.

Roentgen Illustrations of Birth Fractures and Atresia of the Esophagus.—Dr. EDWARD D. TRUESDELL exhibited two roentgenograms showing atresia of the esophagus. The baby from whom the first picture was taken was a full-term child, who when he attempted to nurse suffered from peculiar attacks of choking and cyanosis. Careful examination did not throw any light on the case until an attempt was made to pass a catheter into the stomach. This could not be done and the *x*-ray showed the catheter in the blind pouch which ended at the bifurcation of the trachea and the cricoid cartilage. In the second case the condition was exactly similar. A number of slides were presented showing pressure deformities and fractures of the skull. They had never met with a fissure fracture, all that they had seen having been depressions similar to those of a ping pong ball. Illustrations of microcephalus with irregularities of ossification were also shown. Dr. Truesdell said he had seen ten birth fractures of the clavicle, but that they showed no particular feature; several of them were bilateral and in all union took place. They usually put these up in a figure of eight or a Velpeau bandage. Of particular interest as showing what nature could do in the way of repairing fractures unassisted was a series of plates showing an angular deformity of the humerus resulting from a fracture without displacement. At the end of two weeks there was firm union, but a marked angular deformity. Successive plates showed the angulation becoming less and less, and at the age of two years the humerus was practically normal. The same thing had been shown to occur in other instances. Roentgenograms were also shown of fracture in cases of Erb's paralysis, fracture of the femur, and syphilitic periostitis.

Thymus Obstruction.—Dr. FREDERICK M. LAW said that the first plate exhibited was taken fifteen minutes after death and the findings had been confirmed at autopsy. The child had been operated on for cleft palate, the operation lasting one-half hour. Six hours after the operation the child appeared to be all right. The nurse observed him at this time; then turned to care for a child in the adjoining bed. A few minutes later she looked at the patient and he was dead, having died without a struggle. The plate showed the enlarged thymus of the cap variety holding down over the heart. This was a case of status lymphaticus. A second plate showed an enlarged thymus of somewhat different shape.

Types of Infant Stomach.—Dr. LEON THEODORE LEWALD gave this lantern slide exhibit. He first showed an illustration of an intussusception in an infant. The exact location was not apparent from the physical examination as the tumor could not be made out, but by means of the *x*-ray the tumor was located so accurately that the incision could be made directly over it. At operation the intussusception was found to be exactly where the *x*-ray had indicated. A series of roentgenograms showed the variations in size, shape, emptying time, and the amount of gas in different stomachs of infants. The supreme test of stomach function in infants as in adults was the emptying time. Even peculiar shaped stomachs were able to empty themselves in a reasonable time. The *x*-ray was sometimes a positive help in making the differential diagnosis between pylorospasm and pyloric stenosis, and in deciding whether an operation was necessary or not. The roentenogram from one case showed a small amount of food passing the pylorus; this case went without operation and got well. On the other hand, in another instance it was found that nothing had passed the pylorus in twenty-five minutes, and even at the end of an hour nothing had passed, and it was decided that operation was necessary. Two illustrations of congenital syphilitic stomach were shown. Both children

gave a marked Wassermann reaction. In one of these cases there was a cicatricial area in the lower half of the stomach and an enteroanastomosis was done. The child did well for about a week when she began to vomit and another *x*-ray examination gave the clue to the trouble. The esophagus was found to be very much dilated on account of the small cardiac pouch and by feeding small quantities of food the child finally recovered. Roentgenograms taken two years or more after operation for congenital pyloric stenosis showed the food passing through the gastroenterostomy opening. If one could decide on the proper cases, one need not hesitate to operate since the results had been shown to be very satisfactory.

Hysterical Brachial Monoplegia Following Electrical Shock.—P. Stewart reports the case of a patient who was treated for this condition for two and a half months by various forms of electricity and numerous psychical and sensory stimuli, but without success. On the contrary, the total flaccid paralysis of the left upper limb persisted and the anesthesia advanced proximally on the trunk so as to include the outer part of the pectoral region in front and of the scapular region behind. Suggestive treatment by attempted hypnosis was assiduously carried out for a number of weeks. No improvement having resulted after two and a half months of hospital treatment, it was decided before discharging the patient to try the effect of administering a general anesthetic in the hope of loosening the hysterical obsession during the stage of delirium preceding general anesthesia. Accordingly the patient was placed on a couch with the healthy right arm fixed to his trunk by means of a bandage. Ether and nitrous oxide were then administered, freely mixed with air. Within a few moments the patient began to make purposive movements with the "paralyzed" left arm and these soon amounted to violent fighting movements, in which he endeavored to tear away the anesthesia mask from his face. While the patient was in this excited condition numerous suggestions were made to him that he should move his paralyzed arm in various directions, these suggestions being accompanied by various painful stimuli—*e.g.* twisting the ear, pressing the supraorbital notch, etc. During this stage it was also suggested that his unaffected right arm should become temporarily analgesic to pin-pricks, and this duly occurred. It was then suggested to him that all his sensory and motor symptoms should disappear. On recovery from the effects of the anesthetic patient had lost his previous anesthesia and was able to move both upper limbs in the normal fashion. He has since remained well. The paralysis of the left upper limb has lasted over eleven months from the time of the original electric shock.—*Proceedings of the Royal Society of Medicine.*

Multiple Idiopathic Pigment Sarcoma Treated by X-Rays.—J. H. Sequeira reports the case of a male patient suffering from Kaposi's so-called multiple idiopathic pigment sarcoma, to show the remarkable improvement under *x*-ray treatment. The case was an early one, characterized chiefly by chronic purplish infiltration of the feet and ankles, and to a less degree of the wrists and backs of the hands. There were a few small nodules upon the generally infiltrated areas. The *x*-ray treatment was begun in August and was repeated at somewhat irregular intervals. In all, each part affected received about 50 H units, the applications being made through a screen of aluminum 0.2 mm. thick. There had been no reaction. The condition of the infected areas was now completely changed, the skin was of normal consistence, and the purplish tint had gone. Beyond some brownish staining of the parts there was no evidence of the disease.—*Proceedings of the Royal Society of Medicine.*

Therapeutic Hints.

Treatment of Pulmonary Edema.—J. E. Talley points out that the aim should be to equalize the work of the two ventricles. The pulse tension gives the most important clue to treatment. If there is hypertension glyceryl trinitrate, 1/100 to 1/50 grain, is indicated. Dry cupping of the entire chest should be practised: and if the condition is severe venesection should be performed, a small amount of blood being withdrawn, but as much as 400 to 600 c.c. may be removed. It may be advisable to inject with the glyceryl trinitrate morphine sulphate, $\frac{1}{8}$ to $\frac{1}{4}$ grain. If there is much cyanosis oxygen is useful. Atropine, 1/100 to 1/50 grain, is commonly recommended in acute pulmonary edema. The chief objection to its use has been its marked vasomotor stimulant influence, with consequent rise in blood-pressure. This effect is avoided if a large dose, 1/50 grain, is used. In patients with rapid feeble pulse and evident hypotension quick diffusible stimulants as aromatic spirit of ammonia, whiskey, citrated caffeine, camphor, and even digitalis hypodermically are to be used. In this condition atropine has not even a theoretical contraindication. Morphine, oxygen, and the dry cupping should be used. As regards suprarenal extract, Kinnicutt and Forchheimer reported that it acted favorably, but Meltzer and others have condemned its use, inasmuch as in experimental work suprarenal extract produces acute pulmonary edema. In view of these conflicting results it would seem advisable in acute pulmonary edema to use suprarenal extract only as a last resort. Haven Emerson has recommended the use of artificial respiration if there is cardiac insufficiency. In the type of pulmonary edema associated with subcutaneous edema heart stimulants and diuretics are usually indicated. In the chronic and recurrent form the salt-free diet should be given a trial.—Musser and Kelly: "Handbook of Practical Treatment."

The Legume Treatment in Diabetes.—Marcel Labbé has found that a leguminous diet is of particular service in the treatment of diabetic patients in whom malnutrition is marked. The following daily regimen is ordered: dried legumes, 300 grams; butter, 150 grams; 5 or 6 eggs; 5 or 6 aleuronat rolls or 30 grams of gluten bread. The legumes (peas, beans, or lentils) should be well baked in order that they may be easily digested. It is not necessary that they should be served in the form of a purée unless the patient's digestion is very weak. The above ration suffices for three or four meals. It should be repeated for at least three days, and even for a week with good results. In simple case of diabetes without nitrogenous denutrition, this method of treatment occasionally causes a rapid disappearance of the glycosuria. It is of particular service in the case of hearty eaters. In diabetes with moderate denutrition the legume treatment leads to a diminution or an arrest of acidosis. In the cases of denutrition with acidosis the treatment is of particular value. The treatment is carried out usually for three or four days and is repeated every ten or fifteen days. The effect of the legume diet is similar to that produced by the oatmeal cure, but is superior in these respects: the diet is better borne, is more satisfying to the appetite, maintains the patient's strength to a greater degree, diminishes to a great extent the glycosuria, and combats more effectively the nitrogenous waste.—*Revue de Médecine.*

THE TREATMENT OF ADVANCED PULMONARY TUBERCULOSIS.*

BY S. ADOLPHUS KNOPF, M. D.,

NEW YORK.

PROFESSOR OF MEDICINE, DEPARTMENT OF PHTHISIOTHERAPY, AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; VISITING PHYSICIAN TO THE RIVERSIDE HOSPITAL-SANATORIUM OF THE NEW YORK HEALTH DEPARTMENT, ETC.

I DO not believe that I need to present an apology for the selection of this subject. I believe we all are more or less guilty of the neglect of this class of cases. By saying this I do not wish to imply any wilful neglect or lack of sympathy on our part, but I rather wish to convey the idea that in our enthusiasm to cure the early and apparently curable cases we fail to study and search for more and better means to render the lives of the advanced and often seemingly hopeless cases more comfortable.

I do not blame the many sanatorium directors of private and also of municipal or state institutions for preferring to have their institution known as one for early cases only. We all like to obtain good results, we all love to have our statistics make the best possible showing with the greatest number of cures or at least arrested cases. But to treat and care for the advanced case, to make him comfortable, diminish his suffering, prolong his life, and even make it happy and when possible to bring about a decided improvement, is also worth the while. And last, but not least, by taking good care of the advanced case in a special hospital, sanatorium, or a suitable home where isolation can be carried out, we diminish an important and often dangerous center of infection.

In the treatment of an advanced case whose condition demands care in bed for the greater part of the time, there is to my mind nothing more essential than to have two beds, one for the day time and one for the night. Each bed should be comfortable with covering according to season. In winter there should be used a device to support the heavy coverings, arranged in a manner so as to keep the feet and body warm and still not interfere with the comfort of the patient (Fig. 1).

While fresh and constantly pure air is as essential for the advanced case as it is for the early one, I consider the exposure of a patient in the last stages of the disease to the cold, biting air of the winter months unnecessary and rather inhumane. There are occasionally a few individuals suffering from pulmonary tuberculosis in the advanced stages who like to be out of doors or have their windows wide open in midwinter, but these are relatively few in number. As a rule, their anemic condition makes them very susceptible to the cold from which they suffer unless the room they are in is comfortably warm. In the homes of the well-to-do and in sanatoria, beds can be arranged and placed so that the patient can have the necessary amount of fresh air without suffering from the cold. An indoor window-tent, such as it was my privilege to devise some years ago, is to my mind the only means by which we can render the poor consumptive fairly comfortable at his home (Figs. 2, 3, 4). The amount of incoming cold air and the egress of warm air can be regulated so that the patient will not be subjected to drafts. If the patient is obliged to take his meals in bed, he should be propped up in a comfortable manner (Fig. 5), and the window should be closed when it is cold out of doors so that the room can be warm while he takes his meal. If it is possible, the patient's bedroom should be in close proximity to toilet and bathroom. At night he should be supplied with a urinal and a larger receptacle into which he can empty it so that he will not be obliged to leave the warm bed and be exposed to sudden changes of temperature.

For the well-to-do advanced case of tuberculosis, desiring to be cared for at home, there are several types of newer constructions for outdoor sleeping devices which seem to me particularly adaptable because they can be attached directly to the bedroom. When the weather becomes inclement the patient can walk or be transferred into his bedroom and on the return of fair weather he can occupy anew his outdoor porch.

There is first the comparatively cheap and light construction known as the Mitchell porchet, of which I give an illustration (Fig. 6), and which is self explanatory. It can be easily attached to any building, particularly frame buildings. The weight of this porchet is between 300 and 350 pounds. It is manufactured by the American Porch Construction Works, 305 East Madison Street, South Bend, Ind. Similar arrangements can be obtained with the aid of the so-called "Hanging Sleeping Porch," made by the Korff Manufacturing Company, Lansing, Mich., and the Robert Henry Manufacturing Company, of Pueblo, Colo., known as the Henry Sleeping Porch.

The Co-Ran Fresh Air Bed is also an ingenious device, enabling the patient to sleep out of doors when the weather is mild, and indoors when it is either too cold or too stormy, or when the patient for some other reason desires to remain indoors. Hence it is particularly adaptable for the advanced cases of tuberculosis. The bed rests in a small alcove, extending outside about 2½ feet. The dome-shaped ceiling of the alcove revolves, and by simply swinging it around to the inside the occupant finds himself out in the open, protected by a heavy wire screen and adjustable storm curtains. By reversing the operation, the bed is again inside (Figs. 7, 8, 9).

In New York City, where the fire laws are very

*Read before the Clinical Section of the National Association for the Study and Prevention of Tuberculosis, Washington, May 7, 1914.

severe and strictly enforced, a wall house or star-nook, made of corrugated iron, makes an ideal out-door sleeping device. I am showing a photograph of the one I am using myself. The four illustrations of it (Figs. 10, 11, 12, 13) show how this device serves

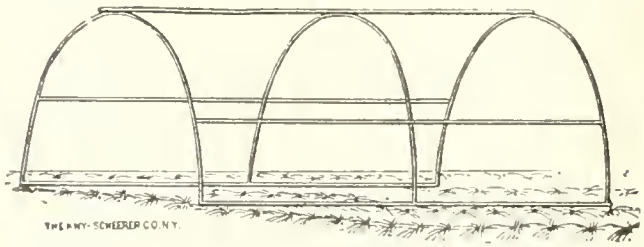

Fig. 1.—Device for supporting heavy bed-clothing.

in all kinds of weather and how its shutters are manipulated to allow free access of air and still assure absolute privacy. In order that all these devices have easy access and exit, it is essential that the window communicating with the outdoor sleeping arrangement should be cut down to the floor and changed into a door so that the patient can walk or be carried easily from the bedroom and back again.

The patient should have a pocket flask with water-tight cover preferably of oval form and metal, so as to be unbreakable (Fig. 14), which he can place under his pillow ready to receive his expectoration. This will do away with the necessity for him to reach out from the warm bed and bend over, thus exposing his back to the cold when he is obliged to expectorate. He should also have within easy reach some soft and slightly moistened cloths to wipe his mouth after having expectorated, or to directly receive the sputum, if manipulating the pocket flask is too much of an effort for him.

The garments which the patient wears in bed should also be according to season. Whenever the circumstances of the patient permit its use, I recommend the linen-mesh underwear and night-gowns. I prefer this material for two reasons. The linen-mesh material allows a freer respiratory action of the skin and the linen material will dry much more quickly when moistened by perspiration than cotton, wool, or silk. An additional pleasant feature of this underwear is an agreeable sensation produced by the friction of the linen-mesh on the skin. It goes without saying that a patient must always have two

Fig. 2.—The Knopf window-tent in position with patient in bed looking through celluloid window into the room, but breathing out-door air only.

sets of underwear—one for day time and one for night. Although there are various weights of linen-mesh on the market, in the advanced cases even the heaviest is not sufficient to keep the patient warm. Under such conditions I recommend the patient to wear one of his old cotton, silk, or flannel shirts over the linen-mesh, the latter to be in contact with the skin.

In winter woolen socks will help to keep the patient's feet warm, and in cold weather the patient

Fig. 3.—The Knopf window-tent when not in use.

should never enter the bed without its having been previously warmed. It is remarkable how even the advanced cases can stand the cold air much better if the bed is thoroughly warmed before the patient gets in and if a hot water bag is placed at the feet and one near the chest to keep him warm during the night.

In warm weather, or rather let me say, in hot weather, an electric fan, when properly placed, will often give an infinite amount of comfort to the suffering consumptive in the latter stage of the disease. Little down pillows placed under the small of the back for a while, or in other places, often give great comfort to the sufferer who is obliged to remain in bed all the time. Of course, in some instances rubber air cushions may become necessary.

The care of the skin of these patients is essential to avoid bed sores and other unpleasant complications. A weekly or semi-weekly inunction with some non-irritating oil, fat, or emulsion (olive oil, lanolin, or white vaselin) will act as a good preventive of skin erosions. Face, hands, and hair should be kept clean and tidy. No male patient in the advanced stage should wear a beard, and if he does not

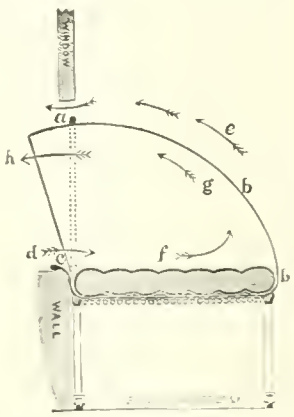

Fig. 4.—Diagram showing ventilation of the Knopf window-tent.

wish to part with his mustache he should at least have it closely clipped.

To diminish any possibility of the spread of the disease by infection of personal or bed linen, everything that comes in contact with the patient should

be of a material that can be boiled and easily washed. For this reason I strongly disapprove of the practice of letting the patient sleep between blankets instead of sheets, and I furthermore recommend that all blankets and comforters, puffs, etc.,

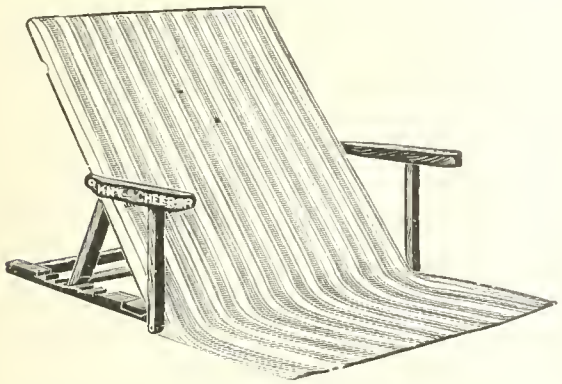

Fig. 5.—Adjustable back-rest.

should be covered with sheeting or slipped into large cases made for the purpose which can be easily removed and washed when soiled with sputum and saliva.

The room which is selected for the patient should, if possible, have a pleasant and cheerful outlook. To remain in a bed from which he can see nothing but the four walls is depressing often to the extreme. While the walls should preferably be oil-painted so that they can be washed off from time to time, they need not be without decoration or pleasing and cheerful pictures; and while I am opposed to fixed carpets and heavy curtains, a rug or two and washable curtains should be permitted. Let us not make the room, which in many instances must be the last home of the patient, into a cheerless place, resembling a prison cell more than anything else; but on the contrary, let us make the private rooms or the wards destined for advanced cases as attractive and as beautiful as possible.

It goes without saying that there must be protection against flies and mosquitos in the sick room of the consumptive. If the patient sleeps out of doors, his bed should be screened in summer and all precautions tending to do away with the fly pest should be taken. The sputum receptacles used by the patient should always be covered to make the access of flies or other insects to them impossible. Patients sleeping out of doors or with the windows wide open are often awakened by the glaring light. I know of nothing better to prevent this annoyance than to place over the eyes a band of some light weight black material and I find the leg of an old lisle thread stocking the most convenient thing, as this material is least heating of all.

The symptomatic treatment of the advanced case is perhaps the most important of all, for it is the numerous symptoms which accompany a pulmonary tuberculosis in the last stages and the complications which arise that tax our skill often to the utmost. There is first the distressing cough. In the earlier stages we may teach our patients to master their cough by discipline and insist that they should never cough unless they feel that they have to expectorate. But all those who have had experience with advanced cases will bear me out when I say that it is a very difficult thing to discipline a cough in the last stage of pulmonary or laryngeal tuberculosis. Nevertheless, the patient should be told to make an effort to control useless coughing (when he does not feel that he has to expectorate) either by a quick inhalation, by holding his breath, or by taking sips of cold water or small pieces of cracked ice.

Now what can we do to make the cough less painful or less frequent? There are besides the hygienic measures—air and quiet—some dietetic ones. I know that an increased ingestion of chloride of sodium, which has a very beneficial influence on the tenacious pulmonary secretions which are so often productive of violent and painful coughing, is a valuable dietetic adjuvant in the symptomatic treatment of pulmonary tuberculosis. It not only acts beneficially on the pulmonary secretions in rendering them less tenacious, but also has a tendency to counteract the demineralization which is always characteristic of a tuberculous disease. An individual eating much salt is, of course, also obliged to ingest more liquid and this in turn helps to counteract the often obstinate tendency to constipation in the tuberculous individual, on which topic we will speak later on.

A hot orangeade taken early in the morning, immediately after awakening, acts likewise as a pleasant expectorant. It aids the patient to get rid of the pulmonary secretions accumulated over night. He will naturally cough a good deal at that time, but the cough will be made easy by the hot orangeade, and after having made this "toilet of his lungs," so to speak, in the morning, he will be relatively free from cough during the day.

Some patients in the latter stages of the disease cough so violently that every muscle in their chest becomes sore and this is accompanied by a succussion of the entire thoracic frame. Under such conditions nothing feels more grateful to the patient and relieves his suffering more than a tightly drawn flannel band around the chest. If the pain is limited to one side of the chest, strapping the affected side with adhesive plaster will also give relief.

I cannot offer anything new in the medicinal

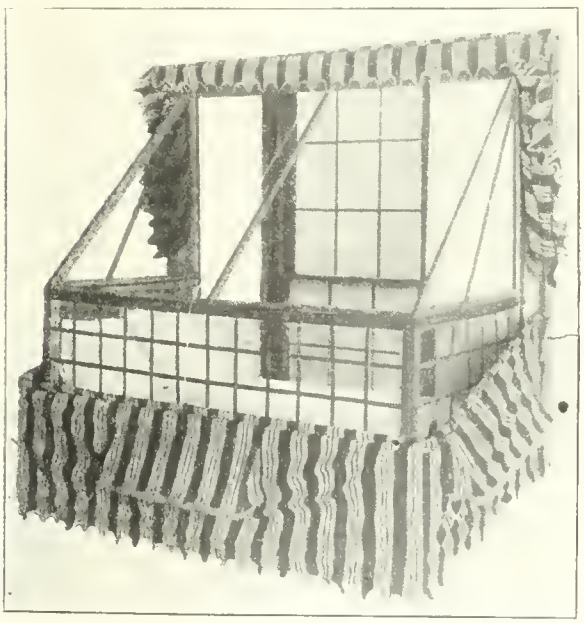

Fig. 6.—Mitchell porchet, can be adjusted so as to be suitable in all kinds of weather.

treatment of cough. Nearly all expectorants are good, and in many instances it becomes necessary to combine them with heroin, codein, or morphine. But before resorting to any of the well-known cough mixtures, I invariably try to obtain relief with in-

halations, and my favorite one is the eucalyptus oil, 3 parts, the spirit of chloroform, 2 parts, and the menthol, 1 part. Of this I give 15 to 25 drops on a Beverley Robinson inhaler or on a handkerchief, to be inhaled several times a day for 10 to 20 minutes.

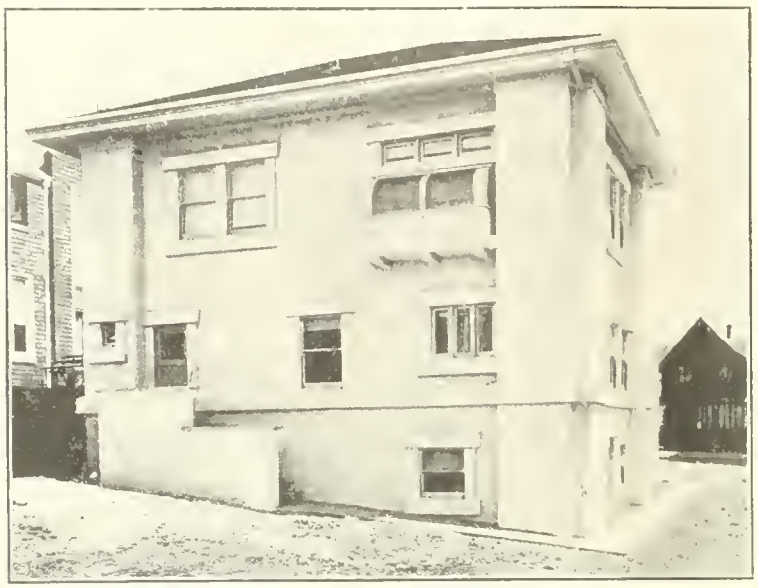

Fig. 7.—Co-Ran fresh-air bed attached to upper floor.

If the patient has no objection to the odor, the menthol can be replaced by the beechwood creosote. Sometimes the steam atomizer, medicated or non-medicated, can be advantageously used in tenacious cough. King recommends the following:

℞	Creosote (beechwood)	6%
	Menthol	2%
	Oil eucalyptus	12%
	Tinct. benzoin Co.....	80%

A teaspoonful of the mixture should be added to a pint of boiling water in an inhaler or croup kettle, and the vapor inhaled.

A gaseous pineen ozonide ($C_{10}H_{16}O_3$) produced by combining pure ozone and the officinal oleum trebinthinæ rectificatum of the pharmacopeia, which was recently presented to the profession by Dr. Bertram H. Waters, of New York, has in some cases of advanced pulmonary tuberculosis under my observation been quite helpful in combating tenacious and persistent cough. It has also proved of beneficial influence in the secondary anemias and as a general tonic to the enfeebled system. The general benefit of terpezone action is probably due to its germicidal powers on certain pathogenic microorganisms, which, by their association with the tubercle bacilli, are the cause of the distressing symptoms of mixed infection.

The anemia almost invariably accompanying the advanced stages of tuberculosis may be combated dietetically and medicinally. Raw, scraped beef, spinach, lentils, peas, cooked by the steaming process so as to have all the salts contained in the vegetables retained, the iron tropone (an albumen food product), tincture of iron, ovoferrin, and the various arsenical preparations, given in small doses, are the best means at our command for the symptomatic treatment of anemia.

In treating the distressing dypnea and thoracic pains we meet with so often in the advanced cases of pulmonary tuberculosis, I have found the old-fashioned dry-cupping a most valuable remedy. Sometimes the vague and undetermined pain can be relieved by a wet pack consisting of a cold compress over the apices and a wider one around the thorax, the whole covered with flannel. I like this better than the typical Priesnitz compress with its intervening layer of oil-silk. I do not favor the actual cautery recommended by French phthisio-therapeutists, nor blistering, nor the too frequent application of iodine. I would rather give the mustard plaster the preference. Of course, in some instances the dyspnea and pain are so intense, particularly in the last stages, that strychnine, nitroglycerin, or morphine alone will give relief.

High temperature in the advanced tuberculous cases is another symptom most exceedingly difficult to combat. Fresh air, repeated partial sponging with lukewarm water every two hours, particularly in the afternoon, the ingestion of plenty of cold water, ice bags or coils with circulating cold water over the head and over the heart, pyramidon in 3 to 5 grain doses 3 to 4 times a day, according to indications, are in my experience the most efficacious remedies ordinarily at command.

Against the troublesome night sweats, likewise a result of mixed infection, the fresh, pure, and cold air, whenever we can get it and if the patient can stand it, is our best non-medicinal remedy. The fact that sometimes the advanced case of tuberculosis, when accustomed to outdoor life and cold weather, feels best in the coldest weather has made

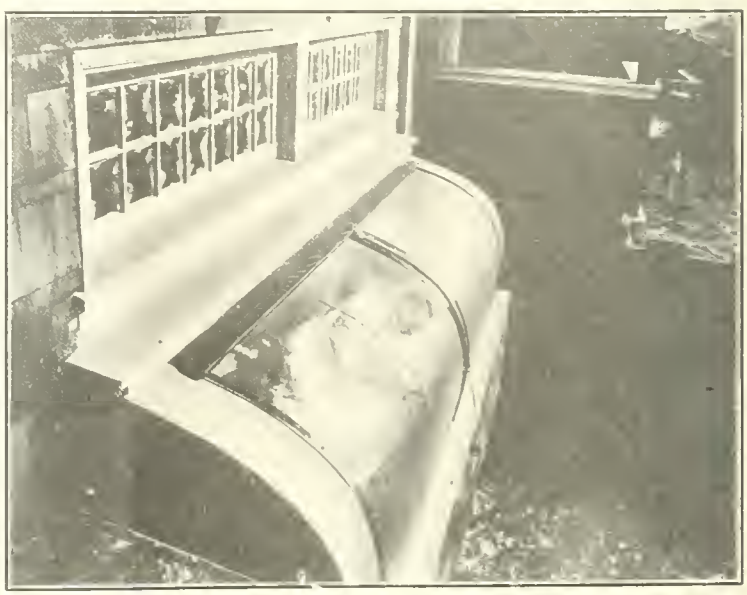

Fig. 8.—Co-Ran fresh-air bed with patient outdoors.

me think that if we could arrange in our sanatoria some sort of artificially cooled air chamber where the temperature could be graduated, and here place our highly febrile cases, we might perhaps be able to count a few more recoveries or at least improve-

ments. When medicine is needed, the atropine tablets of 1 100 or 1 60 of a grain, 5 grain powders of agaricine, or the same quantity of pyramidon may have to be resorted to to combat hyperhydrosis. A little dietetic adjuvant which I have often found helpful with my phthisical patients when suffering from night sweats, is a midnight luncheon consisting of a glass of milk and one appetizingly arranged sandwich for the patient to take when he awakes weakened because of perspiring.

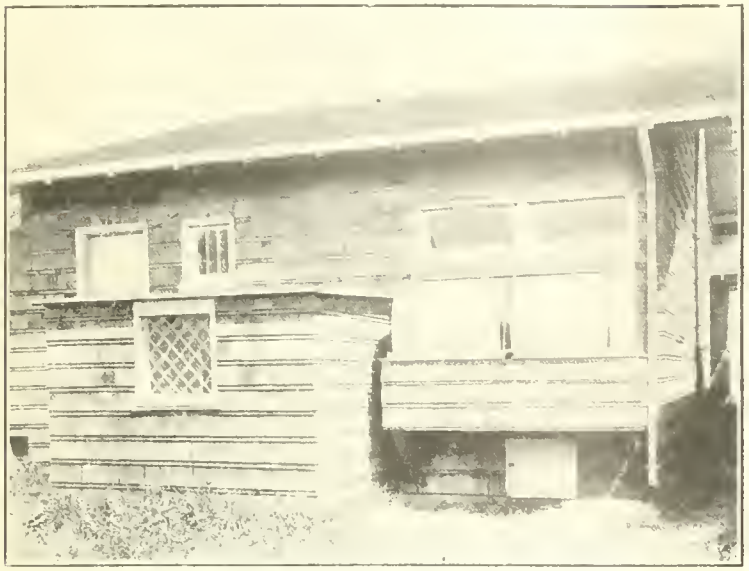

Fig. 9.—Co-Ran fresh-air bed with patient indoor.

Artificial pneumothorax, with a view to compressing the most affected lung to diminish the absorption of toxins and thus diminish fever and night sweats, must be considered as one of our most valuable modern therapeutic means in treating advanced pulmonary tuberculosis. Unfortunately we do not always succeed in performing a successful therapeutic pneumothorax because the advanced pulmonary case usually presents numerous pleuritic adhesions which make the entrance into the intrapleural space exceedingly difficult and sometimes impossible.

Insomnia, when not merely due to the distressing cough, can often be overcome by taking one of the well known hypnotics, such as trional or veronal with hot milk a few hours before retiring. One should, however, remember the depressing influences of these drugs and only give small doses and not constantly.

The gastrointestinal disturbances which manifest themselves almost invariably in the advanced cases will task the ingenuity of the attending physician. One will not only have to examine carefully the character and composition of the stool to discover possible dietetic errors and correct them, but must also study very intimately the idiosyncrasies of the patient appertaining to certain foodstuffs and his likes and dislikes. Sometimes the patient's intestinal tract has been impaired by overfeeding.

Anorexia, flatulence, and constipation alternating with diarrhea, may be the result of more functional disorders due to tuberculous invasion of the intestinal tract. One thing always to be thought of in combating anorexia is the oral hygiene. The teeth must be kept in as good a condition as possible. They should be brushed after each meal and the mouth kept clean by refreshing cleansing washes. A light mixed diet is the first thing to be insisted upon. Tonics may be indicated, and one of my favorite prescriptions for this condition is the following:

℞ Tinct. nucis vomicæ 5ii
Tinct. cinchonæ
Tinct. colombæ .....aa 5i
Tinct. gentianæ. ...q. s. ad. 5iv

M. S. One teaspoonful in three tablespoonfuls of water before meals.

Constipation in the tuberculous must be treated the same way as in other persons—first dietetically by ingestion of more liquid and the use of whole-wheat bread and stale or hard crusted bread, instead of the typical American doughy white bread, more fruit, and vegetables cooked by the steam process. If this does not suffice, medication becomes necessary, but it must always be varied. One should never give the same remedy a long time in succession, but rather alternate with calomel, the saline preparations, castor oil, cascara sagrada, etc.

Ten to fifteen drops of diluted hydrochloric acid given in one-third of a glass of hot water with meals will often help functional disturbances of

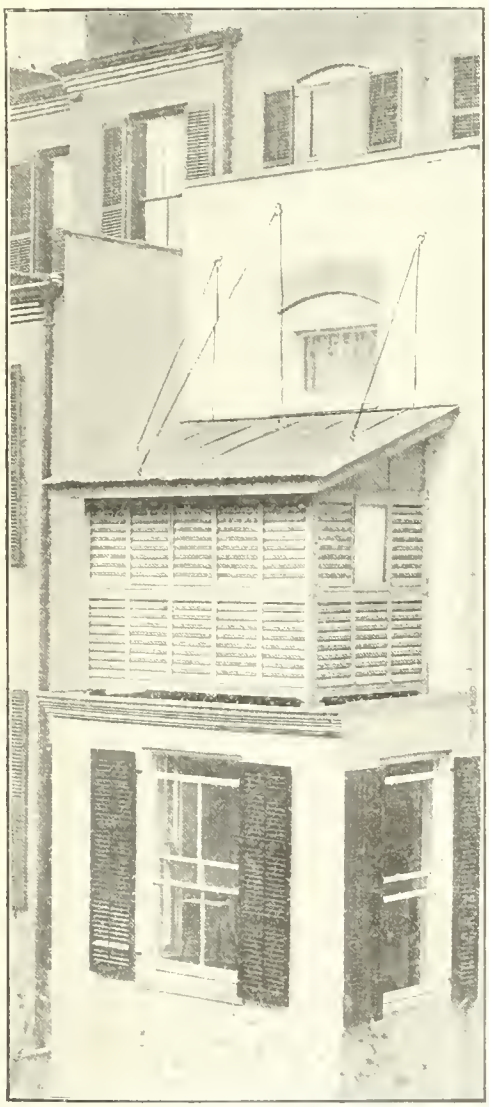

Fig. 10.—Wall house or "star-nook," Knopf model; particularly suited for the treatment of advanced cases at home.

digestion. Flatulence and diarrhea will be benefited by leaving off the carbohydrates in the diet; a mere milk and vegetable diet will prove valuable in combating this trouble.

The typical intestinal tuberculosis must be

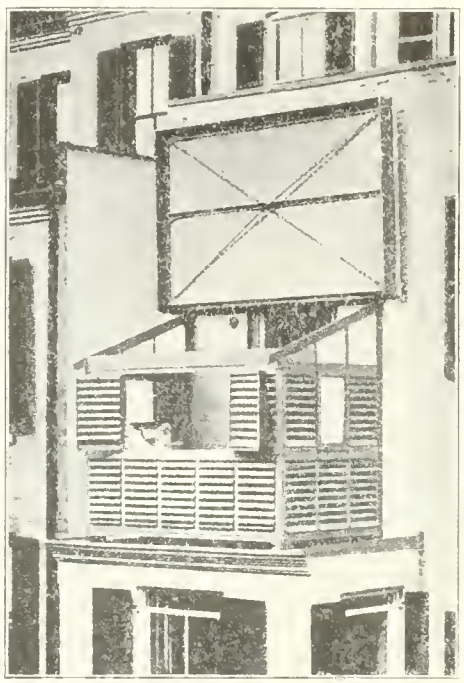

FIG. 11.—"Star-nook" transformed from a night-shelter to a pleasant rest-cure porch by day.

treated with careful liquid or semi-liquid diet; fruit and green vegetables should be avoided. The following two prescriptions are the ones which have rendered me the best service:

℞ Pulv. opii ..... gr. iii
Bismuthi subnitrate 5iss
Sodii bicarbonat ..... gr. xlv
M. F. in chart No. 9.
Sig.: One powder three to four times a day.

℞ Pulv. opii ..... gr. vi
Acid tannici 5i
M. F. in chart No. 12.
Sig.: One powder every 4 to 6 hours, as needed.

King, in his article on Tuberculosis in Forchheimer's "Therapeusis of Internal Diseases," says that colonic irrigations with silver nitrate (1 5,000 solution) seem to have a palliative effect in certain cases and may be tried.

Pulmonary hemorrhage in the advanced cases may vary in degree and duration just as it does sometimes in earlier cases. Quiet in bed and the controlling of the cough is, of course, indicated, no matter whether the hemorrhage is slight or severe. Morphine will perhaps always remain the most important remedy in pulmonary hemorrhage, and locally the application of ice to the chest wall, particularly over the heart, should also be considered indispensable. Emetine (hydrochloride ¼ to ½ gr.) or coagulose may also render good service.

In a severe pulmonary hemorrhage, the immediate thing to do is, of course, to ligate the upper and lower extremities with the aid of a silk handkerchief, flannel band, or some instruments specially devised for that purpose (Assalinische Schnallen) to diminish the flow of blood to the thorax. These ligations of arms and legs are made as near the trunk as possible, and just tight enough to hinder the return of the venous flow, but not to compress the arterial pulse. Every half hour or so, the bands should be loosened, provided a too painful compression of some nerves or a threatening anemia of the brain does not demand an earlier removal of the ligatures. Under ordinary circumstances these constricting bands can be renewed after short intervals as often as the condition of the patient may indicate. A hot water bag should at the same time be placed at the feet. To lower the arterial pressure the pituitary extract might be advantageously resorted to. If the reverse effect is desired, that is to say, if the hemorrhage has about ceased and there has been a considerable shock and a cardiac stimulant is indicated, adrenalin might be given in small doses, for example 5 drops of a 1 1000 solution.

In constantly recurring hemoptysis when there seems to be no tendency to clot formation, the use of fresh horse or rabbit serum' seems to be of value. I have only had experience with the fresh horse serum, and found that 15 to 25 c.c. injected for two to three days consecutively was most efficacious. Dr. M. Nicoll, Jr., who is in charge of the laboratory for making and distributing sera for the Health Department, and through whose courtesy I came into possession of the serum, writes me concerning the indication for the use of horse serum in hemoptysis as follows: "The cases that seem to respond favorably to the action of the horse serum are those who have a steady oozing from their lungs with occasional small hemoptysis. The ordinary procedures, *i.e.* rest, sedatives, ice, of course should not be omitted. The average dose for an adult should be 10-20 c.c., given hypodermically every 12 to 24 hours until results have been produced—say up to six or eight doses if necessary; 50 to 100 c.c. have been used I think unnecessarily and with no better result than from smaller doses. A serum rash perhaps with some rise of temperature may be expected in many cases. No bad results have, to my knowledge, followed the use of serum for this purpose. In asthmatic cases a few drops should be used at first and ten minutes allowed to elapse

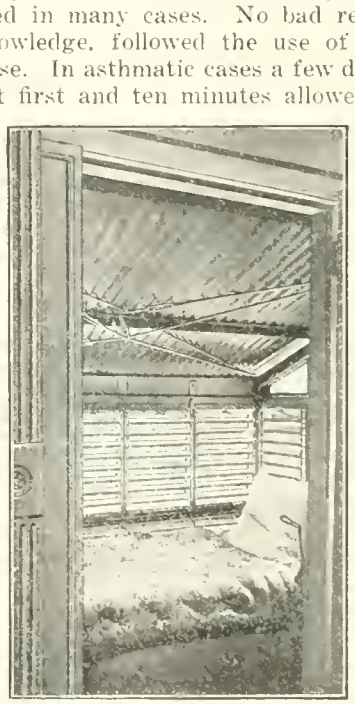

FIG. 12.—Interior of the "star-nook" with windows, roof, and shutters closed; view from adjoining room.

before giving the full dose in order to ward off the danger of anaphylaxis."

Of course, when it is possible to perform an artificial pneumothorax there seems to be no remedy which acts more promptly to check a seemingly un

controllable hemorrhage than this operation. I had remarkable success in a number of such cases with this procedure.

I have nothing new to offer in the treatment of the complications which so often arise in the advanced case. I refer to grippe, pleurisy, and pneumonia. Preventive measures are perhaps most important after all. During influenza epidemics let the patient not be visited by friends, nor nursed, or cared for by nurses or doctors suffering from the grippe, no matter in how slight a degree. The prophylaxis of pleurisy or pneumonia as intercurrent troubles in phthisical patients is more difficult, yet here too we can often guard against exposures and sudden changes of temperature.

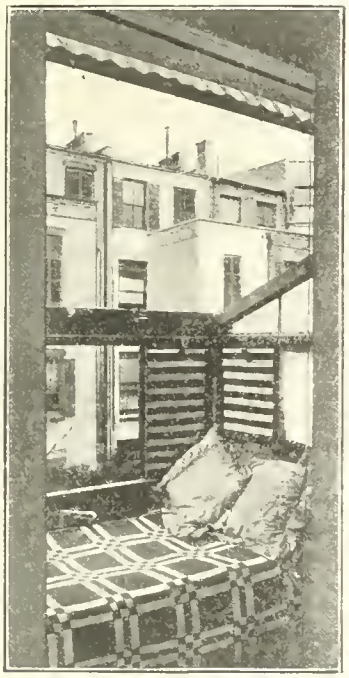

Fig. 1.—Interior of the "star-nook" with windows, roof and shutters open. View from adjoining room.

Now we come to the most painful of all complications in pulmonary phthisis, *i.e.* laryngeal tuberculosis. So long as the patient can be treated locally it often alleviates conditions to give intralaryngeal injections such as are recommended by Shurley (guaiacol (2½ per cent.), menthol, and camphor, of each 2 grains in olive oil).[2] A local application of a 20 per cent. solution of argyrol may also prove beneficial. Lactic acid, in my opinion, should not be resorted to except in very mild solutions because of its painfulness. For painful deglutition there is nothing better than a spray of 5 to 10 per cent. solution of cocaine before meals. Swallowing may also be made more easy by assuming the Wolfenden position. "The head is hung over the bed and the liquid drawn through a tube from the glass upon the floor. In this manner the patient drinks like a horse." (Shurley.)

The local ulcers can often be touched with nitrate of silver, and Freudenthal even recommends fulguration for the cure of these tuberculous laryngeal ulcers. When the patient becomes so weak as to make local application impossible, or they are no longer effective, one may resort to deep injections of alcohol into the region of the nerves supplying the larynx.

We have up to date no better means to relieve the distressing symptoms in advanced laryngeal tuberculosis. The injection of alcohol is now successfully practised by a number of laryngologists and phthisiotherapeutists. E. A. Davis recommends for this purpose a solution of two grains of eucaine in an ounce of 80 per cent. alcohol. Hoffman of Munich, who originated the treatment, uses the alcohol at 85 per cent. without the eucaine, and Freudenthal also omits the eucaine.[3] It would seem that Davis' method is to be preferred.

The modus operandi is as follows: The patient is placed on his back with the head and neck slightly extended. By pushing the larynx toward the affected side the most painful spot can usually be detected with the finger. Then the chin is turned away from the side which is selected for the injection. To avoid sepsis the skin in the region of the nerve is painted with iodine. The larynx is pressed out of the mid-line by the thumb and made to project on the side about to be injected. The nerve is marked out by the nail of the index finger, which is placed between the hyoid bone and the thyroid cartilage and immediately above the superior thyroid tubercle. The most painful spot is once more determined and into it the blunt needle of Schlosser's syringe is pushed with a jerk at right angles

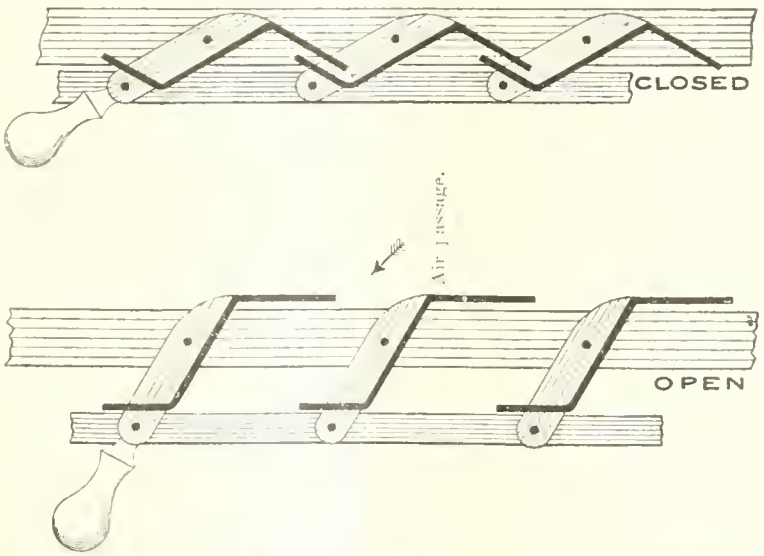

Fig. 14.—Diagram showing the mechanism of the movable iron slats of the "star-nook." (Knopf model.)

to the surface and at the middle of the finger nail to a depth of $1\frac{1}{2}$ cm., *i.e.* to the mark on the needle. A strong blunt needle should always be used so as to avoid injury to blood-vessels and the breakage of the needle. The needle is carefully moved so as to seek the spot on touching which the patient complains of pain in the ear. A few drops of the solution of alcohol are injected, and if there is a violent fit of coughing it indicates that the needle has possibly entered the pharynx and is too deep, but this very rarely happens. Finally, the slightly warmed alcohol solution (heated to about 112° F.) is injected until the pain in the ear has ceased. The initial pain after first injection is sometimes quite severe, but after its cessation a second injection can be made when the patient will feel little or no pain whatsoever. About 1 to 2 c.c. is generally sufficient.

If necessary, both nerves can be injected at the same sitting, but as a general rule it is wiser to allow a few days to elapse before the injection of the second nerve. As an additional precaution, it is well to tell the patient before the operation to be absolutely quiet, neither talk nor swallow while the operation is being made. When the operator has been successful in striking the external branch of the superior laryngeal nerve, the operation is usually

FIG. 15.—Oval water-tight nested flask; it can be manipulated with one hand.

followed by almost complete cessation of pain and the ability of the patient to swallow liquid and even solid food without any discomfort. One injection suffices as a rule to relieve the laryngeal pains for a period of from four to five weeks, after which the operation should be repeated.

On the indications of tuberculin in laryngeal and pulmonary tuberculosis large volumes and lengthy papers have been written and I am surely not expected in the short time at my disposal to elaborate on this subject. At the same time, my paper would be incomplete were I not to say a few words regarding this culture product. I agree with Shurley who in his latest contribution to Forchheimer's "Therapeusis," when speaking of modern "so-called specifics in tuberculosis," says: "Tuberculin, the double-edged sword, stands out preeminently as the most useful remedy discovered up to the present time," and until we find something better, tuberculin administered in small doses so as to avoid reaction would seem indicated in laryngeal as well as in pulmonary tuberculosis in cases where all other means seem to have failed; providing, of course, the patient is willing to have the treatment.

Baldwin of Saranac Lake, one of our best authorities on the subject, summarizes his attitude toward tuberculin in a few but very impressive words by saying: "First, tuberculin may work much good in some patients by lessening the sensitiveness to itself. Second, it may act as a stimulant to healing, or third, it may aggravate the disease."

However, before any physician attempts to use tuberculin I would advise him to study the subject most carefully, not merely by reading the literature but if at all possible by seeing it used with his own eyes and seeking an opportunity for a short visit to a hospital or sanatorium to personally observe the selection of cases, the modus operandi, and the effects of tuberculin therapy. I am not the only one who feels strongly on the possibility of great mistakes being made with tuberculin in inexperienced hands. King of Loomis, another of our high authorities on the subject, expressed himself regarding the danger of the indiscriminate or injudicious use of tuberculin as follows: "Tuberculin is a powerful toxic agent and one capable of doing much harm if improperly used. Only those physicians who are willing to devote considerable time to the study of the subject and who have had experience in observing and handling tuberculous patients should attempt its use."

Whether the old tuberculin (O.T.), the new tuberculin (T.R.), the bacilli emulsion (B.E.), or the bouillon filtration (B.F.) is used would seem immaterial as the same results have been obtained with any one of these culture products.

In spite of our conviction that there is no specific climate for any type of tuberculosis, it would be folly indeed to underestimate the value of certain climatic conditions which the accumulated experience of many years has shown to be advantageous in the treatment of tuberculosis. There does not exist a specific, but there exists an ideal climate for tuberculosis, and it can be described in a very few words. Where there is the least dust and most freedom from smoke and noxious vapors in the air, where the temperature and general atmospheric conditions allow the patient to remain out of doors the greatest number of days out of the year and the greatest number of hours out of the day with the greatest possible comfort and enjoyment, that is the ideal climate for the tuberculous invalid. To some patients this may mean a higher, to others a lower, altitude; to some a cooler, to others a warmer, zone than the one in which they live or have contracted the disease. Individualizing is as essential here as in any other therapeutic measure in tuberculosis.

Whether or not there is an indication for the removal of the advanced case to another climate will again depend entirely upon the individual case. If he is well-to-do and desires a change of climate, his wish should be gratified; the same consideration should be given to him as to whether or not he wishes to go to a sanatorium or have the sanatorium treatment installed in his home. For the vast majority of our advanced tuberculous cases, who are the poor, I believe in institutional treatment near their homes where they can be seen frequently by their friends and relatives without too much expense to the latter. However, a large number of municipal or state institutions for the treatment of advanced cases are in need of vast improvements in many respects. First of all, I would wish to call such an institution a "hospital-sanatorium" to take away that feeling of distinction in the minds of the tuberculous poor to which they have been educated by ourselves, namely, that the sanatorium is

for the curable and the hospital for the incurable cases. Let us give a ray of hope even to the poor consumptive in the latter stage by this more hopeful name "hospital-sanatorium." Let us make these institutions for our consumptive poor attractive, even beautiful, and above all comfortable so that the patient will not miss his home and that his relatives and friends can feel that the place where he is, is a good place for him to be. Occasional entertainments, music, or moving picture shows, an instructive and interesting lecture, anything that may tend to divert the patient's mind from his affliction, or may give him happy moments, should be resorted to. Let all that human skill, sympathy, and kindness can do be done for him there.

The life of the consumptive in the advanced stages, even under the best conditions, is not an enviable one, and one of the greatest difficulties is how to occupy him. If he is a well-to-do patient, and still up and about, let him cultivate some kind of a hobby which is not injurious to his physical condition but will keep him busy. In the afebrile hours he can do a little walking, botanizing, gardening, farming, or anything he likes which will not overexert him physically. In inclement weather he can read, write, use the typewriter, bind books, play on instruments if he is musical; the woman patient can do all kinds of needlework, providing she does not assume a stooping attitude. Non-exciting games of cards, chess, checkers, or dominoes should of course also be permitted. Although not a smoker myself and inclined to discourage smoking, and particularly cigarettes in early cases, I do allow the advanced case of tuberculosis to smoke to a moderate degree if this helps to make him happy and contented.

Much ordinary housework in the private home I do not think advisable for women in the advanced stage of consumption. In a public institution for advanced cases, where the work can be more closely supervised by the attending physicians, a greater variety of occupations for male as well as female patients is of course at their disposal. Patients can help the nurses to keep rooms and wards in proper condition and help in the dining room; they can help the patient ill in bed. In my service at the Riverside Hospital-sanatorium where the vast majority of patients are in the advanced stages, patients do raffia and reed work, and as a rule they take to this occupation most enthusiastically, hardly ever tiring of it. Very often the patients are able to dispose of their products by sale, thus earning a little money which increases their incentive to work. It is rather interesting to note the fact that because we have not sufficient occupations for the men at North Brother Island, not a few of them have taken up raffia and reed work, and some have quite excelled their sisters in this work.[6]

In order that the advanced tuberculous patient who is up and about should enjoy whatever work he does, it is best to have it be something the same as the work he had done when in the prime of health, providing, of course, it was congenial, it is not absolutely injurious to live in his present condition. The one thing which must always be impressed upon the patient's mind is that he should never do any kind of work when he has high fever or when the work he is doing causes a serious rise of temperature. Another good rule, particularly for the advanced case, is never to work when tired nor to the extent of getting tired. Of course, some patients with a lazy tendency may claim to be always tired and they may need to be impressed with the value of occupation as a therapeutic means when their general condition permits them to work.

The authorities in charge of institutions for the treatment of advanced cases should select physicians of experience in tuberculosis, men and women with sympathetic hearts and cheerful and optimistic dispositions, and they should exercise the same care in selecting their nurses. Self-sacrifice, devotion, patience, at times firmness, but always combined with sympathy, are the essential qualities of those who must be in attendance on the advanced case of pulmonary tuberculosis. By the judicious, skillful and humane treatment of these cases we will not only make the lot of the unfortunate ones much happier, but will diminish countless centers of infection and thus solve the perhaps most important phase of the tuberculosis problem of our day. There should be no uncared-for tuberculous patient in any stage of the disease, and there most certainly should be no consumptive sufferer living in lodging houses,[7] boarding houses, or tenement homes, for such persons should be immediately taken care of in a hospital-sanatorium. No municipality can make a wiser and more economic provision than to treat the advanced cases among the poor at the proper place, and no philanthropist could possibly render a greater service to his community than by helping in the establishment and maintenance of sanatoria for the advanced cases of tuberculosis.

16 WEST NINETY-FIFTH STREET.

EFFECTS OF 40 YEARS OF CHOLELITHIASIS.

BY GEORGE HOWARD HOXIE, A.M., M.D.,

KANSAS CITY, MO.

IT is rather unusual to secure the opportunity of studying the viscera of a patient who gives an authentic history of having suffered from gallstones for over forty years. In the following case the patient had been attended by competent physicians, so that the diagnosis had been clear for years.

The interesting findings are those that show the effects of the disease on the neighboring and related organs. They have a bearing on the present-day discussions of abdominal pathology, particularly in reference to the causation of gastric ulcers and to the diagnosis of "gastritis."

Mrs. D. C. C., æt. 63, short, stout woman, quick and active. Complains of indigestion and constipation. History of attacks of colic since about 20 years of age, varying from one to several each year. Has always refused operative interference. Three years ago had an attack of "gastritis," when she was in bed several weeks.

Seen first April 3, 1913 in gallstone colic. Recovered promptly. Next attack April 11, 1913, not severe enough for morphine. The patient was put on hydrochloric acid and cascara which she continued for some weeks. Had an attack of "neuritis" in the right arm

May 11, 1913, which yielded to heat and methyl salicylate locally and diet and cathartics systemically. Gallstone colic June 9, 1913. On July 29, 1913, had an attack of severe diarrhea with temperature to 102 , pulse 116. After this she spent a week or so at Excelsior

Fig. 1.—Gross appearance

Springs and while still troubled with "discomfort" was free from severe colic until September 15, 1913. Again on September 30, she had an attack in which she complained chiefly of pain under the right scapula and as a girdle just above the waistline. Vomiting severe. I was called again on October 1, 1913, and found that a severe attack had come on just as she was recovering from the last. Drugs kept her quiet but the attack did not pass away. On the 2d the pulse was 100; temperature 98.6 . She complained chiefly of pain "in the liver." The epigastrium and posterior aspect of the liver region were very tender to pressure. I gave a hypodermic of morphine and hyoscine. After two hours the patient became stuporous and two or three hours later her temperature suddenly rose to 104 with a pulse of 130 scarcely perceptible at the wrist Peripheral stimulation restored the radial pulse and in the evening the temperature was 102 in the axilla; but the patient did not regain full consciousness. Abdomen bloated and liver dullness gone. Gall-bladder region exquisitely tender. On the 3d the patient was restless, only partially clear, hiccough, vomited coffee grounds. Feces had odor of foul pus and had that appearance. Heart regular. Gall-bladder region exquisitely tender. Patient collapsed, became unconscious, skin cyanotic, irregular respiration at 1 P. M. and pulse did not again appear at wrist.

Blood examination at 3 P. M. showed Hb 90; white corpuscles, 38,500; polynuclears, 89 per cent. no eosinophiles, no mastzellen; mononuclears, 11 per cent. Of the polynuclears 15 were immature, 54 were normal, and 20 vacuolated and amphophilic in type. She died at 4 P. M. and a post-mortem examination was held at 8 P. M.

Autopsy Notes.—Woman, gray hair, appearing to be about 60-65 years of age. Yellowish tint to skin. There are a few blotches on the skin of the chest suggesting a slight purpura. There are no scars. The main cut shows a panniculus adiposus about 1½ inches thick.

The anterior mediastinum contains an abundance of fat. The heart is not dilated. The wall of the left ventricle near the apex is the seat of a fatty change over an area of about the size of a quarter and extending about ⅜ inches into the muscle substance from the surface. The valves are normal, as is likewise the ascending aorta. There is about an ounce of straw-colored fluid in the pericardium. The lungs are compressed and the left broadly adherent to the apex, the right less so. The compression is due to the elevated position of the diaphragm, which is at the level of the fourth costal cartilage. The lungs show no change beyond a moderate pneumokoniosis along the lines of the lymphatics.

The intestines are covered by the great omentum which is adherent below to the left semilunar fold by a rather tough connection. It is also adherent to the gallbladder. There is no fluid in the abdomen and there are no signs of general peritonitis. The right lobe of the liver is markedly smaller and the left slightly larger than normal, especially by comparison. The liver is of a greenish-yellow color, seems to be atrophied. On section it is yellowish-white as if having undergone fatty change. The perilobular tissue is yellowish-white. The liver is not greasy on section.

The gall bladder is dilated to the size of an ordinary 16 candlepower electric bulb and many stones are felt in the region of the cystic duct, which are readily movable to any part of the viscus. The wall of the gall bladder is thickened and is for the most part free from adhesions to the surrounding tissues. As the cystic duct is approached dense adhesions are encountered to all the surrounding tissues and stonese are felt along the common duct. The latter is dilated to about the size of two lead pencils. On dissection dense adhesions are found along the common duct and about the head of the pancreas. When these are cleared away it is found that the head of the pancreas is quite inflamed and necrotic, being very soft, hemorrhagic, and disorganized. Imbedded in this necrotic mass is an angular gallstone impacted and obstructing the common duct and ready to rupture through at one point (Fig. 1). As the entrance to the duodenum is approached the pancreatic duct is found below the impaction, of normal appearance, and patent. As the common duct enters the duodenum its walls are much thickened. The thickened ampulla of Vater lies above the opening of the duct of Santorini. The portal vein shows no thrombosis or other alteration. The pyloric end of the stomach is the seat of an old scar and is slightly thickened. No pus is anywhere encountered. The hepatic duct is normal. The gall bladder contains viscid dark bile and 40 stones.

The stomach is small at the pyloric end and enormously dilated at the cardiac end, apparently being

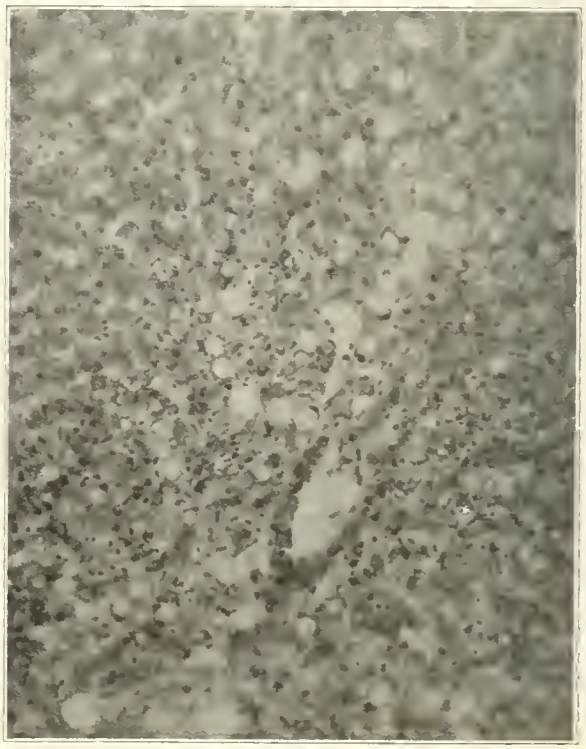

Fig. 2.—Liver

the cause of the elevation of the diaphragm. It contains fluid ingested shortly before death. The spleen is of normal size and consistency, is freely movable and on section is normal. The left kidney is apparently normal. The right kidney is slightly enlarged and on

section oozes freely with blood and is injected (congested). The uterus and adnexa are the seat of senile atrophy, but are normal. The appendix is normal and the cecum is dilated, freely movable, and free from adhesions.

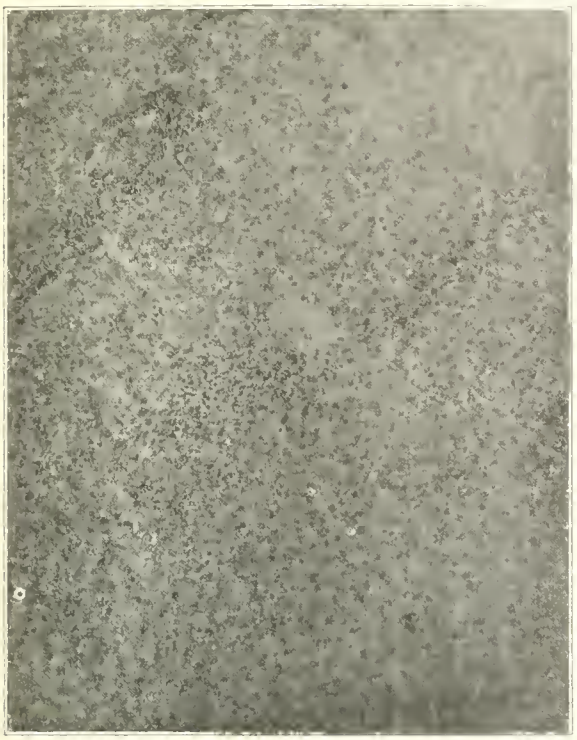

Fig. 3.—Liver.

A strong, tough band lies just above the cecum, constricting the lower end of the ascending colon and is attached laterally to the parietal wall and medianward to the root of the mesentery.

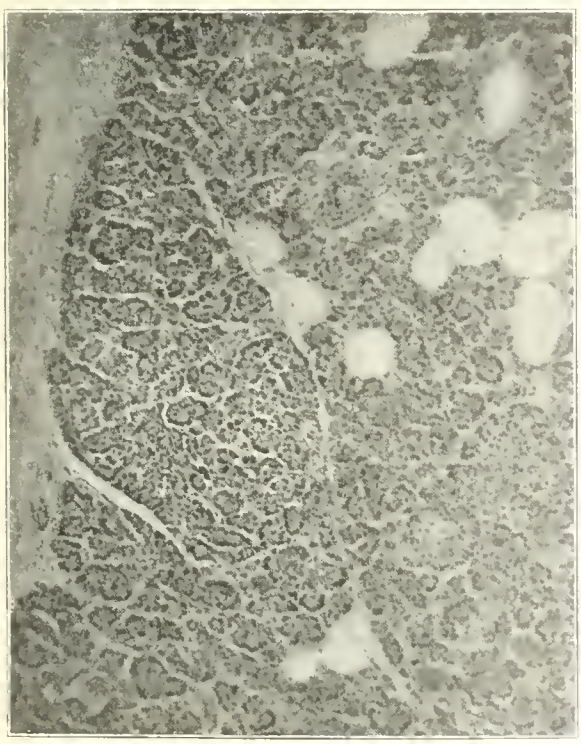

Fig. 4.—Pancreas.

Anatomical Diagnosis.—Acute pancreatitis with necrosis, impacted gallstone in common duct, local peritonitis in the region of the bile ducts and bladder, multiple gallstones in bladder and in cystic and common ducts, yellow atrophy (?) of the liver due to fatty degeneration, congestion of the right kidney, fatty infiltration of the heart, partial thickening of pylorus, partial obstruction of ascending colon due to constricting band, acute dilatation of the stomach.

Histological Studies.—Liver shows round cell infiltration of periacinic vein and fatty degeneration of discrete cells throughout the liver, apparently preferring the neighborhood of the branches of the portal vein (Figs. 2 and 3).

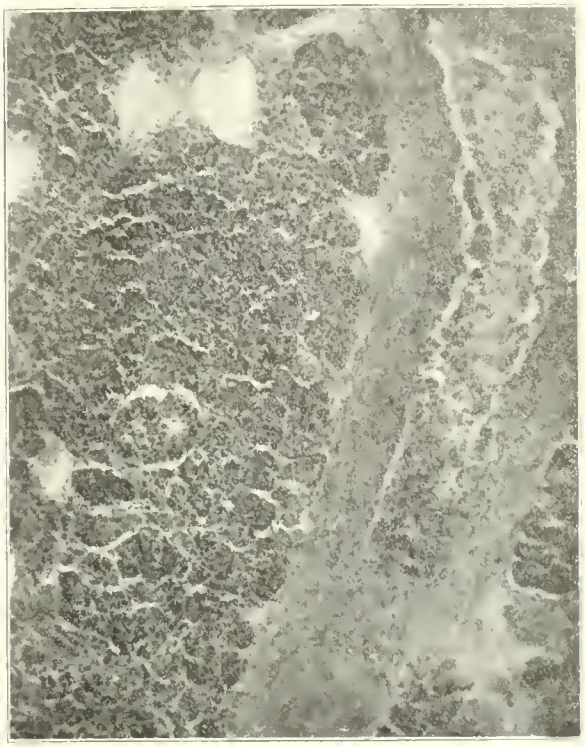

Fig. 5.—Pancreas.

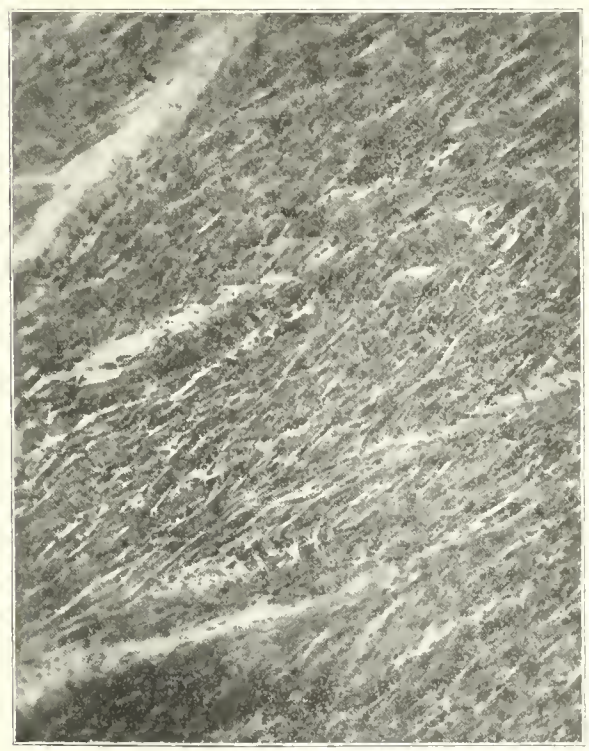

Fig. 6.—Heart muscle.

Left kidney shows some cloudy swelling but in general is quite normal. Right kidney cloudy swelling and glomerulitis. Head of pancreas shows fatty degeneration of individual cells (lipomatosis?). Tail of pancreas shows thickening of interstitial tissue of the in-

teracinar as well as the interlobular type of Opie. Lipomatosis also pronounced (Fig. 5). Areas of heart muscle show fragmentation of fibers and an apparent increase in the number of nuclei. In the accompanying illustration (Fig. 6) may be seen something of the round cell infiltration.

The need of a careful differential diagnosis between perforated gall bladder and pancreatitis is emphasized by this case history. The various medical men who saw the patient in her last hours accepted without much question the diagnosis of perforation as the explanation of her collapse. We were therefore distinctly surprised to find that the stone had not perforated the wall of the duct, but had set up an inflammation of the head of the pancreas. As we look back at the case it is evident that the location of the pains in the back and the discharge of "pus" in the feces should have put us on the watch for the pancreatitis.

The mechanism of the development of the pancreatitis is worth a moment's thought. Evidently the patient had had repeated attacks of pancreatitis with a more or less chronic (subchronic) inflammation always present. This is shown clinically by the history of fever and diarrhea; and anatomically by the evidence of the presence of both the interlobular and interacinar types of chronic inflammation (Opie's classification). The cause of the inflammation was probably the irritation provoked by the various stones ploughing their way down the common duct, together with the constantly increasing pressure of the dense adhesions.

Whether or not the constipation (caused by the band about the colon) had a part in causing the pancreatitis cannot be decided from the evidence at hand. But the lack of abscess formation would militate against such an hypothesis—for in that event colon bacillus infection would surely have occurred.

The duodenal ulcer preceding by three years the patient's death is quite evidently one of the effects of the chronic lithiasis. And in this case the cause of the ulcer must be looked upon as mechanical rather than infective, as an interference with the circulation (and nutrition) of the duodenal portion of the gut. It will be noted that it healed readily, so that the attending physician's diagnosis escaped without question.

The constipation was the result of the band over the ascending colon and also of the adhesions of the omentum. Whether or not the constipation preceded the cholelithiasis must of course remain unsettled. But granted that the original cholecystitis had been preceded by a slight constipation, then the very obstinate constipation that had prevailed for the last twenty years (or more) of the patient's life must have been aggravated by the chronic inflammation about the duodenum. The adhesions were evidently the response to passing inflammations, which may or may not have been due to the gallstones.

In thinking therefore of the possible outcome of cholelithiasis we should add pancreatitis to the list. Hitherto we have told our patients that the outcome might be (1) quiescence, (2) perforation, (3) empyema, and (4) perforation into the bowel. The addition of pancreatitis should be made because it explains the malaise, indigestion, localized inflammations of which patients with cholelithiasis are constantly complaining.

My thanks are due to Dr. Darwin Delap for assistance at the post-mortem examination.

1334 Rialto Building.

A SUGGESTION REGARDING THE TREATMENT OF FRACTURES ABOUT THE ELBOW JOINT.

By WILLIS E. HARTSHORN, M.D.,

NEW HAVEN, CONN.

For the treatment of fractures about the elbow joint most authorities agree that the acutely flexed position offers many advantages over the semiflexed. This applies particularly to fractures of the external and internal condyles, the so-called T fracture of the distal end of the humerous and fractures combining these three types or in the form of a comminuted fracture.

Extension at the elbow after fracture, though extremely important, is not so vital to the patient as an amount of flexion which enables him to carry the hand to the mouth. Furthermore, as the securing of extension in its entirety is greatly aided by gravity, the carrying of weights and other occupational functions, it can be regained even if partially lost, while flexion when limited by adhesions is much more difficult to recover.

Fig. 1.

The main danger in the acutely flexed position is that of retaining the forearm in this position for too long a time. Just as in Colles fracture at the wrist proper reduction is of primary importance, followed by early passive motion and massage, so in fractures about the elbow joint of the type mentioned the forearm, once in the acutely flexed position, should not be allowed to remain long enough to permit adhesions to form. For this reason at the end of the first week passive motion and massage should be cautiously applied. This will avoid any but a very slight limitation of extension, and this is in time overcome. It is remarkable what excellent results can be obtained in these cases, especially in children, even when a severe deformity is threatened owing to the character of the fracture.

The method of securing acute flexion here suggested is simply a modification of those previously presented, but has been found useful at the New Haven Dispensary for the following reasons: First, the Jones position with the canvas jacket to which a glove is sewed, into which the hand is inserted to hold it to the uninjured side, while most excellent,

requires, as a rule, especially in dispensary practice, a new jacket to be made for each case. Second, when using the type of dressing suggested by Scudder, of Boston, the cloth swathe employed has been found rather unsatisfactory, as it does not retain the forearm firmly enough in position.

The method outlined below and illustrated by the three figures does this very satisfactorily, especially in children, and is not uncomfortable for the patient to wear.

After reducing the fracture and placing the forearm in the acutely flexed position the steps in the application of the dressing are as follows:

1. The placing of a gauze bandage extending from the wrist to the elbow permitting free movement at the elbow.

2. An adhesive strip is applied as suggested by Scudder, extending from wrist to arm (Fig. 1).

3. Starting at the elbow the center of a strip of adhesive plaster one and one-half cm. wide and of sufficient length to encircle the forearm and arm is placed posterior to the elbow and its ends brought forward to the anterior surface in the same manner as that employed in strapping the knee joint. A second strip is applied overlapping this one-half. This is followed by more strips of a similar nature, gradually ascending until the forearm and arm have been completely covered both anteriorly and posteriorly (Fig. 2). Protected as they are by the gauze bandage previously applied, the adhesive does not at any point come in contact with the skin except at the hand and shoulder.

4. The application of a strip of adhesive plaster five cm. wide along the dorsum of the forearm and over the uninjured shoulder. This holds the hand firmly in position (Fig. 3).

5. A similar strip of adhesive is then applied around the arm and chest just above the elbow (Fig. 3).

The subsequent treatment of the fracture requires:

Fig. 2.

Daily inspection for the first week. At the end of this time the adhesive plaster is removed and passive motion leading toward extension is applied.

If acute flexion can be easily regained the dressing is reapplied, reducing the angle of flexion by substituting a muslin or gauze swathe for the plaster, allowing only the adhesive band illustrated in Fig. 1 to remain.

This is permitted to stay in place for one week longer, when some form of an external angular

Fig. 3.

splint should be applied, which allows adjustment of the angle.

After the second week massage and passive motion are employed each second day until both flexion and extension are approximately normal.

The daily use of the extremity after the fourth week should in time enable the patient to present a practically perfect functional result in the majority of the cases treated.

1138 Chapel Street.

VASOMOTOR DISORDERS.

By WILLIAM HANNA THOMSON, M.D., LL.D.,

NEW YORK.

The physiological interdependence of the various functions of the body is nowhere so fully illustrated as in the mechanism for the distribution of the blood. While the blood flows rapidly through its tubes three times a minute from head to foot, many persons have too great a mechanical conception of the process, because those tubes which consist of the arteries, capillaries, and veins are so different from any other tubes we know. This difference is well shown after the blood has passed through the lungs and has thus become arterialized. Arterial blood is the only kind of blood which the tissues want. Thus all muscles are thrown into a state of cramp if the arteries supplying them are plugged or even contracted by spasm. This cramp will persist so long as the arterial obstruction lasts, and may finally lead to marked wasting of the muscle. If, on the other hand, the obstruction is not complete but partial, instead of cramp we may have muscular stiffness in movement.

We have many examples of these effects in so-called muscular rheumatism. Voluntary muscles are enclosed in sheaths of connective tissues. These sheaths bear the same relation to the muscle that the bark does to a tree. All the blood vessels sup-

plying the muscles must first pass through their sheaths. Now there is no rheumatic myositis or inflammation of the muscles themselves, but instead such inflammation of the sheaths is very common when interstitial swelling compresses the arterioles and thus diminishes the muscular blood supply. According to the case this result may be quite general, or instead, very local. An example of the latter is a rheumatic affection of the deltoid and trapezius muscles of one shoulder which waste and cause the arm to hang down helpless or else with much pain in movement. The first question then is to settle whether the inflammation is rheumatic or not. If rheumatic, the prognosis is always good, no matter how long or extensive the resulting muscular disability may be. The reason is that the poison causing rheumatism is quite soluble and hence can readily be removed by absorption, while that causing gout is insoluble, and therefore is locally deposited. There is often much confusion between the two conditions, because as they involve joints their symptoms may be very similar. Hence we sometimes hear of rheumatic gout, which is as incorrect as designating the patient a Christian-Mohammedan, because rheumatism is due to a toxemia of its own kind, while gout is the result of a perversion of metabolism, particularly in the liver. These two inflammations, therefore, altogether differ in their results. A knee joint, for example, may be severely involved in a purely rheumatic inflammation accompanied with great pain and swelling. If such effects should occur from any other cause than rheumatism, we would have good reason to expect an extensive disorganization of the joint, but if the inflammation be rheumatic, everything may subside within 24 hours, leaving no traces, while the other knee follows in precisely the same steps in the inflammation. But a gouty inflammation does not occur without leaving permanent traces, as if it were leaving its card to signalize its visit. Cases have been reported of only a single attack of gout with the textural changes following its occurrence found years afterward.

Other cases of muscular cramp may be caused by inflammation of the coverings of the spinal cord, particularly of the dura mater. Once in my service at the Roosevelt Hospital I found a young man who had been a telegraph operator lying in bed with the muscles of both arms and legs so rigidly contracted that his knees were forced together until they were ulcerated. Similarly his heels were buried in his buttocks and the fingers forced into the palms of the hands so that the nails grew into the flesh. He begged not to be touched as every attempt to handle him caused such acute pain. I then told my staff that without giving him any medicine we would so free him from his contractions that he would walk out of the hospital. This he finaly did, and on my seeing him again he said that he had gone for a sail on Long Island Sound when he fell overboard and had to swim for his life. I mention this case because we have a very effective agent for remedying muscular contractions, which is by douching the affected parts with warm, not hot, water. When not above the temperature of the blood, water is a remarkable sedative for relieving pain and for causing muscular relaxation. This patient was treated for three weeks with douches of warm water lasting about 40 minutes four times a day with the gratifying results above mentioned.

Quite different from the conditions just described are the serious results caused by even a temporary absence of arterial blood from any mucous membrane tract. I have explained these derangements in the first chapter of my book "Clinical Medicine," where I have discussed the mechanism of that common cause of disease and death which is popularly termed "catching cold." This disorder, however local, is always caused by an interference with a supply of arterial, and not of venous, blood to the part, as was illustrated by the experiment of Overbach, who found that clamping the renal arteries for only 40 minutes so as to obstruct the flow of blood through the kidneys was followed by albuminous urine for 20 days, thus showing that any local shutting off of arterial blood will promptly induce nutritive changes in the territory of that arterial distribution.

Now the arterial flow in distinction from the venous is under the regulation of a special department of the nervous system called the vasomotor nerves. Every practising physician should become well acquainted with the function and distribution of these very peculiar nerves. Thus organs which are in symmetrical pairs, such as the two eyes, the two ears, the two hands, and the two feet, have their vasomotor nerves always associated. If thermometers be placed in the axillæ and then one thermometer be held in the left hand while the right hand is plunged in ice water, the thermometer in the left hand will fall two to five degrees Fahrenheit, while those in the axillæ are unaffected. If the semi-translucent ears of a rabbit are held up to the light, the readily seen pulsations in the arteries of one ear are found to cease at once when the other ear is pinched. Those organs which are not in symmetrical pairs, such as the two lungs, are not associated in their circulation. Inflammation of one lung does not necessarily cause inflammation of its fellow, but a serious injury of one eye is often followed by total blindness on account of the other eye becoming involved.

Another law is that the vasomotor nerves of areas of the skin are associated with the nerves of the parts underneath these cutaneous areas. That explains all the varied uses of surface applications, such as warm fomentations to soothe internal pain or spasm, and the varied uses of counter irritants. A sudden dash of cold water on the abdomen is used to check a dangerous postpartum hemorrhage, of course not by chilling the whole body, but only through the local association of the vasomotor system. Besides these there are also special relations which may be here mentioned. There is a close relation between the feet and the circulation of the pelvic viscera; also between the feet and the circulation of the throat. Hence, no one with an irritable stricture of the urethra should ever get his feet wet. A man may be warmly clothed, but if he sits in a room with his feet wet from walking in the snow he may have a severe inflammation of the throat or a laryngitis soon extending into a bronchitis. One of the great vasomotor centers is at the nape of the neck, for it controls the circulation of the face and head, and hence a cold draught on that part may be followed by extensive derangements in the circulation such as we have described, and is particularly illustrated in the long sequence of disorders caused by sunstroke.

From what has preceded, it is readily seen that the nutrition of the tissue cells may be appreciably disturbed by interference with their arterial blood. Among other serious results is that such areas become the sources of bacterial infection. Thus the

pneumococcus which causes pneumonia is always present in the secretions of the pharynx, but can do no harm so long as the surface of the mucous membrane there is healthy. But let those cells be damaged by withdrawal of their arterial blood, and an easy entrance of the infective agent may occur. This is also true in the case of the diphtheria bacillus which is often present in the throat and nasal passages of healthy persons without causing any disorder, but which promptly does so when the mucous membrane is affected in the way described.

We have seen that the constant supply of arterial not venous blood to a part is absolutely essential to healthy nutrition. We should not be surprised, therefore, that to a special department of the nervous system this important defensive mechanism is assigned. It is evident from ordinary observation that the distribution of arterial blood must be regulated by some special mechanism. Thus it is estimated that when the stomach is actually digesting its contents it must have nine times as much blood as when it is empty. Not only must it have this great increase in the quantity of the blood, but also it must have an increase of nerve power. Thus a deer shot through the stomach while fasting may run for miles, but if shot through the stomach while feeding, it drops at once from fatal shock. The mechanism above alluded to which so governs the arterial circulation according to time needs, is composed of a special kind of nerves called the vasomotor nerves. These nerves ramify on the coats of the arterioles, penetrating them until they reach the muscular layer which is found in all arterioles. Stimulation of these vasomotor nerves causes the arteries to contract, while if these nerves are cut and thus paralyzed, the arteries supplying those particular parts dilate. For the origin and distribution of these important nerves, however, the reader must be referred to works on physiology. We can mention here only the most important facts connected with this subject. Thus there is a general center of vasomotor control in the floor of the fourth ventricle of the medulla oblongata, whose nerves leave the spinal cord at various levels throughout its whole course, but soon connect with centers of the sympathetic system in such an intimate way that the whole class of vasomotor nerves may be properly called a branch of the great sympathetic. It should be further noted that besides ramifying on the coats of the arterioles, minute ganglia belonging to this system are found whenever an arteriole divides, whose function evidently is to contract or to dilate the peripheral vessels and thus control the local circulation.

Another fact of much practical importance is that the vasomotor nerves of any part of the skin are always associated with the nerves controlling the circulation underneath that cutaneous area. It is on that surface that a sedative or stimulant application can be used accordingly, but the converse of this law is also important. Whenever any internal inflammation occurs its effect is equally felt by the nerves of the corresponding cutaneous area. Any internal inflammation, therefore, will cause an increased susceptibility of the corresponding nerves on the skin. I once saw a distinguished clinician expose the chest of a woman in order that his class of students might listen to the rub of pericarditis. He thus exposed the patient's chest so that some twenty students could listen, with the result that in a few hours the woman's life was despaired of from the rapid extension of the internal inflammation. These facts explain the importance of surface protectors such as are commonly used in thoracic disorders, but they may also be applied in chronic abdominal affections. Patients who have been subject to chronic diarrhea and dysentery should wear over the abdomen a shield made of cotton batting, because we often find them particularly susceptible to surface chill.

A physician, therefore, should be well acquainted with all the remedies which we possess for vasomotor disorders. Often these are caused by blood poisoning as we see illustrated in chronic disease of the kidneys. Thus chronic interstitial nephritis causes such permanent contraction of the systemic arteries as to lead to hypertrophy of the heart from the heart's increased work in overcoming this contraction, and this complication must be treated accordingly. We have but few medicinal remedies for affections of the vasomotor system. We have, therefore, to go back to the general law controlling the functions of blood distribution, and we begin with the lungs. Muscular power throughout all animated nature is dependent upon the amount of oxygen taken in by respiration. Insects have proportionally far greater muscular power than any other creatures because they breathe through every part of their skin, and not through a pulmonary apparatus only. In man also the tone of the muscular layers lining the tubes of the body, such as the bronchial and alimentary tracts, are dependent upon the activity of breathing. Women, therefore, are much more subject to weakness of such muscular function than men on account of their sedentary habits. A person standing or walking breathes more than twice as actively as when sitting or lying down, and hence whole classes of persons troubled with poor circulation of the blood would not be so if they were constantly living out of doors, like farmers and sailors.

One of the most useful remedies for derangements of the vasomotor centers is by the proper recourse to the reaction from cold. Cold as a remedy should be defined as an irritant, which is primarily a sedative, but which is followed by reaction so soon as its initial sedative impression is passed. This property of cold gives it what is popularly known as its tonic effect, but in practice its application should always be proportioned to the power of reaction from it. Thus a cold shower bath may be a valuable vasomotor tonic in a young patient because of his vigorous reaction.

We have already referred to the fact that one of the great vasomotor centers is at the nape of the neck. This is particularly exemplified by the long-continued and varied disorders which follow sunstroke. Insolation or sunstroke causes the sufferer to have his whole head and face reddened by very slight causes which could not affect him in health. In addition to this his heart becomes easily disturbed with palpitation, so that he becomes virtually a coward and dreads the least excitement. The mucous membrane of the nasal passages is also seriously involved. The cold douches applied to the nape of the neck will frequently cure a long standing nasal catarrh. Here there is another irritant added, namely, the blow of falling water, technically called a douche. This should be used every morning on rising by the patient, care being taken not to wet the hair. The procedure should be followed by active friction.

It should here be noted that all chronic inflamma-

tions occurring anywhere are particularly apt to produce local weakness of the vasomotor nerves. A knee or ankle, for example, may swell and become weak from its own nerves becoming involved in a chronic inflammation, and nothing restores such conditions better than cold water douches followed by active friction.

70 East Fifty-fourth Street.

THE SUBJECTIVE AND OBJECTIVE SYMPTOMS OF FAVORABLE AND UNFAVORABLE REACTIONS TO TUBERCULIN.*

By MYER SOLIS-COHEN, A. B., M. D.,

PHILADELPHIA.

PEDIATRIST TO THE JEWISH HOSPITAL AND THE PHILA. JEWISH SANATORIUM FOR CONSUMPTIVES, EAGLEVILLE, PA., AND CONSULTING PHYSICIAN TO THE HOME FOR CONSUMPTIVES, CHESTNUT HILL, PA.

Ability to recognize and interpret the symptoms produced by tuberculin is essential in one who would employ this therapeutic agent. It is from the patient's response to the dose given that we are able to study the effect of that dose. Hence unless we note every symptom of this response or reaction, we will miss important evidence as to the effect the particular dose given has had on the individual patient. Many of the phenomena of a tuberculin reaction are often unrecognized because they are slight or have not been recorded in the literature. The physician consequently does not seek for them and even when his attention has been directed to them may attribute them to other causes. In like manner the patient himself may fail to notice them or else may disregard them. Thus valuable information as to suitability or unsuitability of dosage is neglected, with the result that the appropriate dose is frequently increased, instead of being maintained, and the excessive dose often still further augmented, until the well-known book symptoms of a severe unfavorable reaction supervene. Unless the physician questions his patient closely—without, of course, suggesting the nature of the reply—and unless the patient observes himself carefully and reports his symptoms accurately, many of the less well-known symptoms of a reaction will be missed. A valuable guide as to the regulation of the treatment will thereby be lost.

Patients vary so in the manner in which they react to tuberculin that it is practically impossible for any one individual to personally observe all the manifest symptoms that may accompany a reaction. But if the observant physician will note every symptom occurring on the day of and on the day after the administration of tuberculin, that was not present before the dose was given, he may possibly discover symptoms of a reaction of which no mention has as yet been made. When, moreover, one is acquainted with the various described phenomena that may accompany a tuberculin reaction one will be much quicker in detecting and much apter in eliciting them. A symptom that might not have been noticed or might have been ascribed to another origin will receive more careful attention if it has already been reported as having followed the administration of tuberculin in other hands. Hence the more symptoms there are recorded, the more readily will these symptoms be recognized and the more frequently will they be looked for. In order to direct attention to the disregarded and unfamiliar symptoms I have tabulated all the subjective and obective symptoms that have followed the administration of tuberculin in seventy-one of my patients of whom I have sufficient notes and on whose records I could lay my hands. To this list, which contains ninety-eight separate symptoms, I have added twenty-eight more that have been described by other writers but not recorded by me.

I distinguish between favorable and unfavorable reactions to tuberculin and have grouped the symptoms under these two general heads. In regulating dosage I interpret the favorable reaction as meaning that the dose is just right, and a moderate or marked unfavorable reaction as evidenced that the dose is excessive. A slight unfavorable reaction I regard as an indication that the dose is reaching a dangerous point. The absence of any reaction at all I look upon as a sign of an insufficient dose.

Many of the ninety-eight distinct symptoms I observed I have not seen previously recorded. It is, of course, possible that some may not have been a result of the tuberculin, merely appearing coincidently, although I have tried to eliminate such an error. While I state the number of times each symptom was recorded, this is not of much significance, because the patients were questioned only at intervals and the notes often refer merely to the dose immediately preceding their interrogation. Many symptoms may have been present that were not elicited, the patients merely being allowed to tell how they felt, and having no list of symptoms to guide them, such as appears in the tuberculin record books. When a patient appeared in any way unreliable, no attention was paid to his relating of subjective symptoms. This necessitated the elimination of most of the children treated. No attempt has been made to enumerate the number of times temperature changes were observed, on account of the magnitude as well as the uselessness of the task. It should be borne in mind that this is an analysis not of patients taking tuberculin but only of those who presented symptoms of a reaction to tuberculin. A comparison of the number of favorable and of unfavorable symptoms observed would be misleading, as the dose that caused favorable symptoms was always repeated, while the dose causing unfavorable symptoms was always reduced. I find, too, that the more skilled and experienced in giving tuberculin I become the more favorable and the fewer unfavorable reactions do I see.

SYMPTOMS OCCURRING IN SEVENTY-ONE PATIENTS REACTING TO TUBERCULIN (98)

Pain in arms	1	1	1	1
Pain in legs	1	1	1	1
Pain in back	2	2	2	2
Pain in abdomen	1	1	1	1
Cramp in abdomen	0	0	1	1
Cramp in elbow	1	1	0	0
Cramp in knee	1	1	0	0
Cramp in ankle	1	1	0	0
6. Eye Symptoms. (14)				
Inflammation of eyes	0	0	1	1
Feeling as of foreign body in eye	0	0	1	1
Eyes hot	0	0	2	1
Increase in burning in eyes	1	1	0	0
Feeling of hot wave in front of eyes.	1	1	0	0
Feeling as if eyes were blo lshot	1	1	1	1
Throbbing in eyes	2	1	1	1
Soreness or pain in eyes	1	1	0	0
Queer pain in eyes	0	0	1	1
Feeling of and increase of weakness in eyes	1	1	0	0
Things looking queer	0	0	1	1
Brightness of eyes	1	1	0	0
Dilation of pupils	1	1	0	0
Black spots in front of eyes	1	1	0	0
7. Vasomotor Phenomena. (7)				
Flushed face	5	3	2	2
Feeling hot all over	1	1	0	0
Feeling feverish	0	0	3	2
Perspiration all over body	1	1	0	0
Swelling of hands	1	1	3	1
Stiffness of hands	1	1	1	1
Feeling as if wrist and finger were twice their size	1	1	0	0

Increase in the rapidity of the pulse usually accompanied a rise in temperature.

Some patients who showed no symptom on the day of the injection or on the day following, yet lost weight after the dose was increased beyond a certain point, which I regarded as an unfavorable reaction.

A number of symptoms of a tuberculin reaction, reported by other observers, differ in name from those I have enumerated but may, I believe, be included among them. Thus "heaviness," "dulness," and "lassitude" I would include with "malaise." "Feeling of heaviness in the limbs" probably corresponds to "tire" or "disinclination to exert." "Slight tendency to ache" and "severe headache" may be grouped with "pains all over." Symptoms resembling "La Grippe" may be classified with "indisposition" or "symptoms of coryza." "Constriction in the chest" is probably another way of describing what my patients call "oppression in the lower ribs." "Discomfort" is probably synonymous with "indisposition." "Exhaustion" could doubtless be placed under "tire," "weakness," or "faintness."

In addition to these there are twenty-eight symptoms of a reaction described by other writers, which I have not observed, or at least noted.

Symptoms of a tuberculin reaction observed by others but not by me (28). I. *General or Systemic Symptoms* (10): Rapid pulse; delirium; general hyperesthesia; rash, skin eruptions; herpes; herpes labialis; rigor; convulsions in epileptics; enlarged glands; increase in the amount of urine with a slight trace of albumin or diazo reaction.

II. *Pains* (3): Pain or tenderness in epigastrium; wandering pains; pain in throat.

III. *Local or Organ Symptoms* (6): Hoarseness; pain in throat; aphonia; swelling of tuberculous glands; increased frequency of micturition; increase of inflammatory redness in visible places, as in lupus.

IV. *Vasomotor Phenomena* (3): Skin cold and clammy; face cyanotic; face of ashen color.

V. *Skin Reaction at Site of Injection* (7): Definite and prolonged painfulness and inflammation, especially when the injection has been made in the trunk; pain at site of injection; discoloration at site of injection; swelling at site of injection; thickening of skin at site of injection; edema at site of injection.

2113 Chestnut Street.

THE WIDENING PELLAGRA ZONE.

By George G. Hunter, M.D.,

and

Edward Huntington Williams, M.D.,

Los Angeles, Cal.

The recent studies of pellagra, and exhaustive reports such as that of the Thompson-McFadden Pellagra Commission, have undoubtedly resulted in the discovery of many obscure cases of this disease which otherwise would have escaped detection. This statement probably applies to a greater extent in the regions that are supposed to be outside the focal pellagra zones than in places where the disease is of common occurrence. Nevertheless, the number of cases that have been reported at points remote from the focal centers, and the fact that many of the conditions attending these cases do not conform to the observations made in the South, force the conclusion that the disease is not only increasing its territory, but is invading classes that have hitherto remained practically immune.

It is possible, of course, that even in remote districts, where pellagra seems only recently to have

made its appearance, the disease is not really such a novelty, but simply that it has not been recognized heretofore. This is a reasonable supposition, particularly as regards the milder or abortive type of cases. But it can hardly be true of the virulent types. And the natural conclusion is, since well-marked cases are now making their appearance in districts that seem to have escaped hitherto, that the disease is actually extending its zone of operation.

The report of the Thompson-McFadden Commission indicates that the disease is usually the concomitant of malnutrition, poverty, and bad hygiene. "In our opinion," says this report, "the view that pellagra is an intestinal infection, transmitted by contaminated food, to which the individual is rendered more susceptible by malnutrition, poorly selected or poorly prepared food and by the common gastrointestinal disturbances resulting from errors in diet, is a conception worthy of further study."

In most of the cases of this disease that have come under our observation recently the conditions referred to in this report did not prevail, although all of them presented the typical picture of pellagra itself as shown by the two following cases:

Case I.—Mrs. H., a married woman, 37 years old, who has been living in or near Los Angeles for several years, was first seen on July 2, 1914. Has one healthy child seven years old, and has had two miscarriages since the birth of this child at two and three months respectively, the last one about five years ago. She was perfectly well up to two years ago. About that time, however, she began having severe pains in her muscles and joints, shifting in character, but focalizing in the feet, with some burning and swelling. The pains came on in February while the patient was living near Los Angeles, but disappeared in about two months, and she recovered completely. In October following she weighed from 165 to 175. About this time her menses ceased, and she began to have "queer" feelings in her arms, which seemed heavy and useless, with some burning. In December she began having shifting pains again, which continued for about two months; and during this time her child became ill and she nursed it night and day, with the result that she was in a state of nervous prostration. Meanwhile she had become much crippled with the pains which she called "rheumatism." There was no fever. On March first she began having peculiar feelings in her throat and abdomen, and her husband reports that two days later she became very much excited and disturbed mentally. The mental disturbance, with great excitement and at times confusion with definite delusions and hallucinations, persisted. But during the last few weeks she has lapsed into a state of mental delapidation with apparently progressive dementia. Seven weeks ago she developed an extremely sore mouth and diarrhea, said to have followed a dose of calomel. The diarrhea and the condition in the mucous membrane grew worse rapidly, apthous sores appeared all over the mouth, the tongue was swollen and beefy, and at the same time there developed great irritability of the bladder, inflammation and swelling about the vulva with a dull red appearance.

Two weeks after the onset of the gastro-intestinal trouble the patient began developing a symmetrical pigmentation over the knuckles of both hands and along the radial sides of the index fingers. This pigmentation was red like sunburn, the skin was much thickened, and between the thumb and forefinger on both hands some blebs appeared. The same pigmentation occurred over the nose, chin, and cheeks, and the skin became thick and encrusted. There was vomiting frequently. And during these weeks of gastrointestinal trouble the patient had great pain in both legs below the knees, requiring opium as a sedative. She complained constantly of great burning in the feet. The muscles were exquisitely sensitive in the legs and generally over the body, and she walked with a great deal of muscular ataxia. The pupils were small and reacted very slowly to light. The knee jerk, at the time we observed her, was practically abolished; and although the other reflexes were present, they were much diminished. The pulse was rapid, (110-116), but there was no elevation of temperature. This condition continued for about a week after our first observation, when the patient died, seeming to have gone to pieces from exhaustion.

It will be observed that in this case there was no neuropathic taint, although the nervous system was in a very low state of resistance from physical and mental strain at the time of the onset of the disease. In the following case, however, it is apparent that the soil for developing a psychosis was well prepared, both by autochthonous and environmental conditions:

Case II.—Miss S., unmarried, 26 years old, a teacher by occupation, was seen first June 6, 1914. Gives a history of neurotic temperament as a child. She was the sixth of eleven children, but has always been the favored one of the family, and has always been considered "a little queer." About nine years ago she had a nervous breakdown and passed through a period of depression. She recovered from this, however, and was in fairly good health for several years afterward, but with an occasional return of mild depression and nervousness.

In the spring of 1912 she suffered from a great deal of pain up and down her spine and in the great muscles of the back, and at about the same time she had an attack of diarrhea extending over ten days or two weeks without any apparent cause. Shortly after this she placed herself under the care of a chiropractic, but became very much worse. In the early part of her summer vacation she was exposed to considerable nervous irritation and excitement incident to a family reunion at her home, which left her in a very nervous state, the pain in the back having persisted. At this time the trouble seemed to be confined to the severe pains in her back muscles, with a developing tendency to insomnia. By Christmas time there was so much general prostration and depression that she was obliged to give up her work, and a little later went for a trip in the mountains. While on this trip she noticed a beginning pigmentation on her hands, face, and forehead.

A few weeks later under the influence of the sun exposure at the beach she became very much pigmented, at the same time her insomnia and depression became very pronounced, and she threatened suicide. Shortly after this she was placed in a sanatorium. Here she developed very shortly a severe cystitis, with frequent, painful urination, and pus in the urine; and about this time the pain which had been confined to her back for a year became general, with considerable muscular tenderness in the arms, thighs, and calves. Two weeks after the appearance of the bladder symptoms the patient developed an irritation of the lower lip, with marked swollen erythema, becoming dry, cracked, and crusted. A week later an extensive ulceration of the mouth began, with sores under the tongue and throughout the buccal cavity, a thick, beefy tongue, and swollen spongy gums. At this time there was great tenderness all through the abdomen, frequent and persistent diarrhea, loose watery evacuations, with occasionally a little blood-stained mucus. There was extensive inflammation of the genital mucus membranes which were red, swollen, and beefy looking.

The face presented a marked pigmentation extending over the forehead, following the hair line down into the temples, over the malar eminences and over the nose. The skin presented the appearance of a very severe sunburn, but was dry and thickened, with a tendency to the formation of a crust over the nose. And a similar condition appeared progressively over the knuckles of both hands and along the radial sides of the index fingers. These areas were sensitive to touch, and the patient complained that they felt as though seared. She complained also of general sensory disturbance throughout the chest, and a burning sensation in the back and arms.

At this time there was a slight elevation of temperature, from half a degree to a degree and a half, and her mental condition was that of a profound depression with a great deal of restlessness.

In some of the other cases seen personally, or reported in this vicinity, the order and time of appearance of symptoms have been somewhat differ-

ent, but in the main the clinical picture presented has been closely similar.

According to the Thompson-McFadden Commission observers the disease is peculiarly prevalent among women between the ages of nineteen and forty-five, whereas the rate of prevalence among males drops very appreciably at this time of life. The exact amount of this decline is shown by the fact that, although the rate of prevalence is practically equal in the two sexes among children under ten and among adults over forty-five years of age, in the intervening period the proportion of women afflicted is about four to one. The age incidence, and disproportion in number of women, are confirmed by observation of cases on the Coast, although the number of males has about equaled the number of females at the County Hospital recently, as reported by Dr. C. H. Whitman.

It appears, therefore, that the period of woman's greatest susceptibility to pellegra corresponds to the period of her active sexual life. Apparently this occurrence is purely coincidental, although there may be a deeper significance.

Nor is there any evidence to show that neuropathic or psychogenic taints play an important part in the etiology, course, or termination of the disease. Or that occupation can be regarded as a factor, unless we regard as such any occupation that requires physical and mental strain.

But perhaps the most interesting single feature presented by these two cases, as well as by most of those brought to our attention in this vicinity, is the fact that they occurred among a class of persons representing a very different economic status from the majority of the cases observed by the Thompson-McFadden Commission. And the reports of cases which have been supplied by Drs. C. H. Whitman, C. L. Allen, and J. L. Smith of Los Angeles seem to indicate that the patients were largely those from the better walks of life, or at least were persons accustomed to good food and hygienic surroundings of the middle classes.

Certainly the economic condition of these cases contrasts strikingly with those reported by the Thompson-McFadden Commission observers. For these observers report that 85 per cent. of cases occurred among people of insufficient means, who were eating poor, badly prepared food, and where general economic conditions were bad. Probably their findings are distinctly influenced by the relatively high percentage of poverty in the regions under investigation. But in any event it is interesting and significant that the cases seen in Southern California taken collectively refute the old idea that pellagra is largely a "filth disease." Or at least they show that, if the disease was formerly only the accompaniment of poverty, affecting the lower classes, it is now extending its attacks to the more favored strata of society.

The fact that the cases just cited, and the other we have observed, presented intestinal and nervous symptoms of great severity does not warrant the conclusion, of course, that all the cases in this vicinity have been of this virulent type. It is more reasonable to assume that many of the milder forms, in which only cutaneous symptoms were present, have not been recognized.

In considering the early symptoms of some of these cases, particularly those in which the mental symptoms appeared first, we have been impressed with the likelihood of mistaking these symptoms for those of neurasthenia. The differential diagnosis is made more difficult by the fact that the disease often develops slowly, cutaneous and gastrointestinal symptoms are frequently delayed, women are more frequently affected than men, and the age-incidence and economic status (in this region, at least) correspond to those of neurasthenia. With these facts in mind it is easy to understand that perfectly excusable mistakes in diagnosis might occur—mistakes that are far more likely to be condoned by physicians, unfortunately, than by the patient's friends.

THE TREATMENT OF ORBITAL CELLULITIS.

By S. E. PENDEXTER, M.D.,

East Orange, N. J.

Assistant Surgeon, New York Throat, Nose and Lung Hospital.

The treatment of orbital cellulitis, like the treatment of headache, depends upon the cause of the trouble. Orbital cellulitis probably rarely if ever is primary. Then we must look upon cellulitis in this region as a complication of diseases elsewhere. Hence our treatment should be directed to the source of the infection as well as to the orbital inflammation.

Orbital cellulitis may result from penetrating wounds, erysipelas, pustule of the lids or nose, dacryocystitis, lacrymal adenitis, or suppurating periostitis. It may be transmitted to the orbit through the vascular or lymphatic channels. Hence a metastatic process may develop from a general pyemia, or from some remote focus, as an alveolar abscess, or a suppurating inguinal gland. However, a large proportion of cases of orbital cellulitis are caused by extension from one or more diseased accessory sinuses of the nose.

The relative location of the primary cellulitis and these sinuses, or other contiguous anatomical structures, helps us much in discovering the original focus of the infection. A primary inflammation or edema of the upper lid (especially the outer portion), a ptosis palpebræ, or a paralysis of the superior rectus muscle or of the superior oblique muscle, points to an extension from the frontal sinus. In these cases, however, we should exclude other causes, such as lacrymal adenitis and suppurative periostitis. When the initial cellulitis is more marked at the inner portion of the orbit or when there is a paralysis of the internal rectus muscle, the anterior ethmoid cells are the most probable source of infection. But when these signs become manifest, the source of infection may be a diseased lacyrmal sac, a furuncle, or erysipelas. When the primary cellulitis is below the eye, or if the inferior rectus or the inferior oblique muscle is paralyzed, an extension from the antrum is to be suspected. It may be difficult to locate the primary cellulitis; as in any case, the edema or ecchymosis may extend by gravity to the lower lids. Should the infection gain entrance through the posterior ethmoid cells or the sphenoid sinus, there is more apt to be an exophthalmus; or there may be an optic neuritis, or an atrophy of the optic nerve; while the third, fourth, sixth, or all of the motor nerves may be paralyzed. We must take into consideration, however, that a diplopia or an apparent paralysis may be caused by pressure from the swollen tissues, edema, or an abscess, which inhibits the action of the ocular muscles.

The signs and symptoms of the original disease

should be noted, and our treatment should be directed to this condition, before serious orbital or intracranial complications develop. We receive much aid in locating the original focus by the history of the case, location and character of the pain and tenderness, evidence of nasal discharge, inspection of the nares, transillumination, irrigation of the antrum, catheterization of the frontal sinus, or by the *x*-ray.

Foreign bodies should be removed, and furuncles or penetrating wounds should receive treatment under general surgical principles. A periostitis, lacrymal adenitis, dacryocystitis, or other lesion should be treated according to the indications in each individual case. Thrombosis of the cavernous sinus, aneurysm, tenonitis, and constitutional dyscrasia should be confirmed or eliminated to guide us in the treatment of these cases.

An orbital cellulitis, from a disease of the accessory sinuses, is evidence of partial or complete obstruction to their nasal drainage, with retention and pressure from the accumulating secretion and debris. On account of the proximity of the accessory sinuses to the meninges, a vigilant search should be made to ascertain the particular focus to be treated.

Often the intranasal instillation of adrenalin and a cleansing spray, or nasal irrigation, is sufficient to reestablish drainage. However, many cases do not improve with this treatment, or the symptoms may be such that a delay would be dangerous. Then we must resort to such operative procedures as are necessary to procure drainage of the diseased sinuses. This fortunately can usually be accomplished by the intranasal route. Ample intranasal drainage of the ruptured sinuses should be procured and maintained.

Intraorbital complications from the cellulitis, or extension to the meninges or brain should be anticipated, and the method of treatment varied according to the exigencies of the case. An external operation rarely is indicated when there is a persistent empyema of the frontal sinuses or the ethmoid cells, or when there is a threatening meningitis. An enucleation may be necessary, when there is an impending meningitis, and by an enucleation and a large opening there is hope of saving the patient's life.

The cellulitis and edema may be moderated by cold compresses over the diseased orbit, and mild antiseptic applications will ease the conjunctivitis, while hot compresses will increase the local congestion and hasten a delayed recovery. If the chemosis is marked, multiple punctures of the conjunctiva permit the serum to escape and gives a relief which is very gratifying to the patient. Any accumulation of pus should be immediately incised, avoiding actively functionating structures. Liberal catharsis should be procured in all cases of orbital cellulitis.

Case I.—Mrs. M. B., Orange, N. J. This woman on June 6, 1913, had a hard indurated suppurative periostitis, which was firmly adherent to the orbital margin of the frontal bone. The patient gave a history of having had this for the last six months and that the swelling became worse at times, sometimes being so bad that she could not see well from the right eye. The patient was given antiluetic treatment, but when she was next seen by the writer, June 10, the swelling over the eye was more pronounced and there was a cellulitis and edema of the upper lid. To prevent a diffuse orbital cellulitis the abscess was opened and one cubic centimeter of pus was drained out. The probe passed 1½ inches under the frontal bone into the orbit but no dehiscence of the floor of the frontal sinus could be found. The case made an uneventful recovery, and was referred back to the general practitioner as a luetic condition was suspected.

Case II.—Baby R. K., age 27 months. This patient was first seen at the clinic of the New York Throat, Nose and Lung Hospital on June 20, 1913. A diagnosis of orbital cellulitis resulting from ethmoiditis was made. This case responded favorably to the intranasal instillation of adrenalin, nasal irrigation and orbital applications.

Case III.—Miss E. M., age 6 years. This patient was treated at the New York Throat, Nose and Lung Hospital. When she was first seen on December 1, 1913, she gave a history of having had a swelling around the left eye for five days, and around the right eye for two days. Both upper lids were red and swollen, the left side being swollen to a greater degree than the right. The swelling in the lower lids was less marked. The following treatment was instituted. The nasal instillation of a 1 to 2,000 adrenalin chloride solution, and an alkaline antiseptic spray were ordered; while frequent irrigations of the nares with hot normal salt solution were faithfully performed. However, in spite of the treatment the orbital cellulitis became worse. The patient's temperature also continued to rise; on December 3 it became 100° F., and on the 4th the temperature reached 101° F.

The patient was operated upon by the writer on December 4 at 8 P. M. Both antra were irrigated, the return flow containing a small quantity of muco-purulent material from each side. Both sphenoid sinuses were patulous. The anterior tip of the left middle turbinate was removed, and the anterior ethmoid cells were curetted, to make free drainage for the frontal sinus. Much polypoid mucous membrane was removed from the ethmoid cells. The postoperative treatment consisted of the instillation of adrenalin chloride solution, frequent hot saline irrigations of the nares, and the application of cold boric acid compresses to the swollen eyelids. The following day, December fifth, the cellulitis was less marked but the temperature remained 101°. On December 6, the patient's temperature went down to 99.6° and there was much less swelling of the lids. On December 7 the patient's temperature went up to 103.4°, and the lids became very red and swollen. The region of the infundibulum was lightly curetted, without an anesthetic, and much detritus was removed. The postoperative treatment was continued, and on the following day the temperature went down to 100.4°. On the 10th of December the temperature went down to 99.4°, and on the 12th it was normal. When the patient was discharged from the hospital, December 16, the cellulitis had entirely subsided.

Case IV.—Mr. W. A. Adult, South Orange, N. J. This patient was first seen in my office on Jan. 11, 1914. At this time he had an orbital cellulitis on the right side with extreme edema and chemosis. The patient gave a history of having had a rhinitis the previous week, but this had improved. He complained of orbital pain, and extreme supraorbital pain which extended over the brow to the vertex. Intense tenderness, especially on the outer superciliary ridge, was elicited. There was no dacryocystitis, no periostitis, and no evidence of infection from the superficial tissues. A frontal sinusitis was deemed to be the cause of the orbital infection. The anterior tip of the middle turbinate was removed, and the anterior ethmoid cells were curetted, to give free drainage to the frontal sinus. The instillation of adrenalin, and frequent intranasal irrigations were instituted; also cold compresses were applied to the eyelids. On January 12 the pain in the head was less, but the ocular chemosis and orbital pain was worse. The patient had also developed an orbital cellulitis of the left side. Multiple perforations were made in the conjunctiva to relieve the tension. The treatment was continued on the right side, and the same treatment was instituted on the left side. On January 13 the condition was improved. The treatment was continued, keeping the patient under observation. The nasal discharge was profuse at first, but this as well as the cellulitis gradually subsided. On January 25, when the patient was last seen, there was a moderate degree of conjunctivitis; but the lids of both eyes opened freely, and upon eversion only a slight edema of the superior fornices could be observed. There was no abscess formation within the orbit.

New York, October 31, 1914.

THE CLINICAL VARIETIES OF UREMIA.

WHILE rapid strides have been made within recent years in the recognition of the pathological states accompanying or underlying uremia, and in the detection of chemical changes in the body fluids that point to a threatening uremia, there has been at the same time a sharper delineation of the different clinical types of uremia. Emil Reiss in the *Zeitschrift für klinische Medizin*, Vol. 80, Nos. 1 and 2, and 5 and 6, describes three distinct types of uremia and one mixed type. The former are denominated the asthenic, the convulsive or epileptiform, and the psychotic types of uremia.

Asthenic uremia is characterized clinically by somnolence and indifference, by bodily fatigue, by attacks of syncope, and by sudden death from failure of the heart. The elimination of sodium chloride, nitrogen, etc., by way of the urine is disturbed. In the blood there is an increase in the residual nitrogen and in the osmotic pressure. It is probable that the retention of nitrogenous derivatives ordinarily excreted is responsible for this type of uremia.

The epileptiform variety of uremia is recognized by the occurrence of more or less frequent eclamptic seizures which most strikingly resemble those of genuine epilepsy. The aphasias and paralyses of uremia probably belong to this category. The urinary secretion is adequate, and the results of examination of the blood show no departure from the normal. The substances that evoke this type of uremia are not the result of a retention caused by a deficient excretory capacity of the kidneys.

The psychotic type of uremia is distinguished by the predominance of psychic changes, particularly by pronounced mental confusion, by delusions and hallucinations, and finally by deep and not simply agonal coma. The above states are usually transient. In this variety of uremia there is no evidence of the retention of normal metabolic products, and the origin and nature of the toxic substances are still veiled in obscurity. The sclerosis of the cerebral arteries demonstrated at autopsy in many of these cases is to be regarded merely as an accessory factor that favors the occurrence of the above manifestations.

The mixed type of uremia comprises the majority of all the cases, including those which present symptoms belonging to two or more of the first three groups. In the genesis of these cases all the possible causative factors must be borne in mind. Cases belonging purely to the first three groups are relatively rare. Reiss suggests that his classification does not account for every so-called uremic manifestation, and that additional groups may yet be described.

In the majority of cases of uremia the albumin-content of the blood serum, as measured by the Kjeldahl process, equals or exceeds that normally present, even in cases in which efforts have been made to diminish the concentration of the blood by venesection or by an abundant administration of fluids. From this fact, together with the results of other experimental and clinical studies, there is drawn the conclusion that in uremia there is a disturbance in the normal relationship between the water and the dissolved substances of the blood. The uremic patient lacks the capacity to dilute properly his own body fluids. It is this deficiency that the author regards as the exciting factor in uremia.

RECENT INVESTIGATIONS ON THE SUPRARENAL GLANDS.

OF perennial interest is the subject of the physiology of the suprarenal glands, a subject which touches clinical medicine at many angles. In spite of the vast amount of knowledge which has accumulated regarding the relation of the suprarenal glands to the other organs of internal secretion and to the body in general, the conception of the actual rôle of the suprarenals is still veiled in obscurity. For this reason considerable importance must be attached to the researches undertaken by S. J. Crowe and G. B. Wislocki (*Bulletin of the Johns Hopkins Hospital*, October, 1914). They set out to determine the immediate and remote effects of a total removal of both suprarenal bodies in young and in old animals, and the effects of an adrenal insufficiency produced by the operative removal of portions of the gland at intervals of weeks or months.

It was found, first of all, in confirmation of the observations made by other workers, that in the dog the suprarenal glands are vital organs, and that it is probably the cortex rather than the medullary portion which is essential to life. Total removal of both glands causes symptoms similar to those produced by a total hypophysectomy. When a part of one gland is excised the remaining portion undergoes hypertrophy, through the multiplication and enlargement of the cortical cells, chiefly in the fascicular zone. An interstitial fibrosis and a destruction of the cells in the same zone is sometimes observed when there is a chronic infection in an animal suffering from suprarenal insufficiency. Following an "almost total" removal of both glands there frequently occur convulsions, a subnormal temperature, and other symptoms of acute suprarenal insufficiency. From these manifestations the animal may completely recover. Adrenal insufficiency causes no permanent change in the carbohydrate tolerance, although a transient glycosuria always follows operative manipulation of either

gland. No functional value has been perceived in an autoplastic transplantation of a suprarenal fragment when this operation has been successfully accomplished. If both cortex and medulla are present in the graft the cells of the former may survive, but the cells of the latter undergo absorption.

Of eminent significance are the experiments undertaken with the object of determining the relationship between the suprarenal glands and the lymphatic system. Autopsies on animals that had had a long-standing adrenal insufficiency showed an enlargement of the mesenteric and retroperitoneal lymph glands and the solitary lymph follicles of the intestine. In many instances there was observed in addition a hyperplasia of the thymus. These findings are in close agreement with the observations that have been made for a long time in cases of Addison's disease, in which a local or general hyperplasia of the lymphatic system has been noted. The close relationship between the suprarenals and the lymphatic system has been shown in cases of status thymicolymphaticus which have come to autopsy, in which a marked hypoplasia of the chromaffin system has been observed.

Narcolepsy.

The various seizures described under this term differ much among themselves, yet shade into one another by imperceptible gradations. At one extreme is a mere act of "nodding," a momentary absence, which affects children almost exclusively and suggests epileptic petit mal. In certain cases these seizures occur in almost incredible numbers. At the other extreme the subject behaves like one completely exhausted, falling asleep as soon as the attention is fixed by reading or listening, and waking automatically as a result of his constrained attitude which is not suitable for slumber. These subjects usually wake up fully conscious and with no unpleasant feelings. In certain cases sleep seems to be replaced by laughing attacks, which set in during reading or conversation. As a rule, the subjects sleep well at night. At a recent session of the Breslauer psychiatrisch-neurologische Vereinigung (*Berliner klinische Wochenschrift*, September 7), the President, C. S. Freund, presented a case of narcolepsy which appeared to show the close connection between the latter and ordinary sleep disorders. As a child the patient was a somniloquist and somnambulist. She could converse intelligently while asleep. As an adult she could read aloud while sleeping. The narcoleptic attacks supervened as a consequence of reading and listening, and under the same conditions she had laughing fits, even, for example, while expressing condolence. The only connection between falling asleep and laughter appeared to be the automatic element. Epilepsy, hysteria, neurasthenia, periodic paralysis, myasthenia, etc., could all be excluded. There were no evidences whatever of mental failure. The patient, whose age was 56, was much older than the average subject of narcolepsy when she first appeared for consultation.

Nephritis and Nephrosis.

Since it has been asserted that the so-called parenchymatous nephritis is not inflammatory but degenerative in character, various attempts have been made to take it out of the realm of the nephritides. It is admitted, however, that it still constitutes an important subdivision of Bright's disease. Müller proposed the term nephrosis as a substitute for parenchymatous nephritis, for the latter even when preceded by cloudy swelling is degenerative in nature from beginning to end. The blood vessels and glomeruli are hardly involved in the process and the heart does not undergo hypertrophy. There are several other nephroses, notably amyloid kidney. In a paper read at a session of the Aerztlicher Verein of Hamburg (*Deutsche medizinische Wochenschrift*, September 3) Fahr, after isolating the nephroses, as above, divides true nephritis into interstitial and arteriosclerotic, each of which is subdivided so that four types result: 1. Diffuse glomerulonephritis, which is the forerunner of secondary cirrhotic kidney. 2. Focal interstitial nephritis, which comprises several conditions of minor clinical import. 3. Primary arteriosclerotic kidney, which is very variable in degree and associated, as a rule, with arteriosclerosis in general. 4. The combined form, in which marked arteriosclerotic changes may complicate a nephrosis or nephritis. There is still much confusion as to what really constitutes primary or essential contracting kidney.

How to Proceed Against Unlicensed Practitioners.

It sometimes happens that the legal authorities fail to discover an unlicensed practitioner who pursues his calling quietly without attracting too much notice to himself by advertising, and unless their attention is directed to his illegitimate practices he may go on undisturbed for years. He is necessarily known, however, to the lawful medical practitioners of his town or neighborhood, and it devolves upon the latter to denounce him to those whose business it is to repress him. In calling the attention of the officers of the law to the activity of an unlicensed practitioner one should take the following steps: (1) Make sure that the practitioner is not registered in the county clerk's office; the law requires that all practitioners shall register their license with the county clerk. (2) Obtain evidence, sufficient as a basis for a complaint, that the practitioner is attempting to diagnose or to treat human disease, injuries, or physical conditions. (3) Send a written complaint to the district attorney along with a request that he prosecute the illegal practitioner under Section 174 of Article 8 of the Public Health Law. (4) If the district attorney refuses to investigate the complaint, notify the Governor, as he has the authority to remove from office district attorneys who refuse to do their duty.

The Bacteriology of Herpes in Pneumonia.

A short time ago Schottmüller of the Hamburg-Eppendorf Hospital reported a series of cases of herpetic fever in which he demonstrated the colon bacillus as the cause of the cutaneous lesions. In these cases there was a primary focus of infection in the pelvis. Of closely related interest is the investigation which has been carried out by Carlo Trevisanello (*Annali dell' Istituto Maragliano*, June 22, 1914) on the bacterial content of the herpetic vesicles that so commonly develop on and about the lips in cases of lobar pneumonia. He found that cultures made from the contents of these vesicles

contain diplococci in a pure state. These microorganisms are in a condition of attenuated virulence, but may be made to acquire their native virulence by successive passage through experimental animals. They respond to all the tests for the pneumococcus. Of practical significance is the fact that the herpetic lesions of pneumonia may be a potent means of transmitting the disease. This possibility is increased by the fact that the vesicles have delicate walls and, causing considerable itching, are prone to be ruptured by the nails of the patient.

Black Tongue and Its Causation.

The affection commonly known as black tongue is characterized by the presence of one or more blackish or brownish patches in the tongue, which are associated with an elongation of the lingual papillæ. This condition has been attributed to a parasitic cause. A large number of different parasites, chiefly moulds, have been held responsible by various observers. The glossophyton is the one most commonly described as causative of the peculiar pigmentation of the tongue and of the elongation of its papillæ. L. Jannin, in the *Journal de Médecine de Bordeaux*, refers to the theory, held by a number of observers, that this is a neurotrophic disorder, in which an excessive vascularization of the papillæ would cause their hypertrophy with a deposition of black pigment. The growth of the various moulds which have been isolated in these cases would thus be favored by the changed surface conditions of the tongue. Without subscribing to this view, Jannin holds that although the parasitic theory has not been definitely established by scientific proof, it is nevertheless most plausible.

The Protein Metabolism in Experimental Pancreas Diabetes.

A little over one year ago A. Galambos and B. Tausz reported their clinical observations showing that contrary to previous conceptions hyperaminosuria occurs not only in cases of impaired hepatic function, but also in disturbances of the internal secretory mechanism of the pancreas. In a second communication on this subject in the *Zeitschrift für klinische Medizin*, Vol. 80, Nos. 5 and 6, they show that the internal secretion of the pancreas takes a part in the transformation of protein into its normal end-products. An insufficiency of this internal secretion produces a hyperaminosuria analogous to the glycosuria resulting from the same cause. Diseases of the liver and various infections may be accompanied by a similar aminosuria, just as they may be accompanied by an alimentary hyperglycemia or glycosuria. The authors are of the opinion that both hyperaminosuria and glycosuria are based on the same metabolic causes, which may consist in a diminution in the amount of this substance or in the degree of its activity.

News of the Week.

American Surgeons in France.—The American Ambulance Hospital in Paris, under the charge of Dr. Joseph A. Blake of New York, is working up to its full capacity of 400 beds. There is room in the hospital, however, for 1,000 beds and every effort is being made to raise a fund sufficient to provide these. All the American physicians in Paris are assisting in caring for the wounded of all the warring nations who are brought there from the front. Five American surgeons sailed on the *Rochambeau* two weeks ago to enter the French Red Cross. One of them was a woman, Dr. Mary M. Crawford of Brooklyn; the others were Drs. M. J. Sheahan of Derby, Conn., A. S. Cooke of Brooklyn, Barton McC. Cookingham of Red Hook, N. Y., and Thomas Nisbet of this city. Dr. Alexis Carrel of the Rockefeller Institute, New York, is now in Lyons in charge of one of the hospitals there. The cable reports that he recently performed his first transfusion, in the case of a soldier weakened by profuse hemorrhage from a wounded axillary artery.

Mobilizing British Gold.—The daughter of Robert Koch, who is the wife of a German army surgeon, has given the Harben gold medal, presented to her father by the Royal Institute of Public Health of London, to the German Society for the Relief of the Families of those killed in war. The medals presented by English societies to Röntgen and several other German scientists have also gone into the melting pot for the benefit of the Red Cross or relief societies. Professor Max Verworn of Bonn has written to the *Berliner Tageblatt* protesting against the renunciation of British honors by his colleagues, an action which he characterizes as childish and unworthy of German men of science.

Casualties in the German Medical Corps.—The army surgeons of all the nations, but apparently especially of the Germans, have suffered very severely in the present war. Up to the middle of October 135 of the German medical staff were reported killed, wounded, or missing, 74 of these having been killed. In the entire Franco-German war of 1870-71 only 11 German surgeons died on the battlefield or from wounds there received.

Atlanta Medical College.—The sixtieth annual session of this college began on September 28 with an enrollment of 340 students.

Typhoid Fever Due to Bacillus Carrier.—Investigation by the Pennsylvania State Department of Health into a recent epidemic of typhoid fever at Lehigh University at South Bethlehem, Pa., involving forty of the students has disclosed the fact that a kitchen employee was a typhoid carrier and the probable source of infection.

Cerebrospinal Meningitis.—The weekly report of the Health Department states that there has been a sudden increase in the number of cases of cerebrospinal meningitis in this city, ten cases having been reported during the past week. "Reviewing the course of epidemic cerebrospinal meningitis in this city for the past thirty-five years," says the report, "it is noticeable that the intervals between the high points of mortality attributed to this cause are about eleven years. In 1881-82, in 1892-93, and in 1904 and 1905 tremendous high waves of mortality occurred. The increased mortality during the past week may be the forerunner of an approaching epidemic."

Philadelphia Medical Club.—Major-General Leonard Wood, U. S. A., was the guest of honor at a reception held October 16.

Dr. Ellwood R. Kirby has been appointed Chief and Consulting Surgeon to the Masonic Home at Elizabethtown, Pa.

Mental Defectives in New York State.—According to a census just completed by the State Commission to Investigate Provisions for the Mentally Defective, there are 8,399 mentally defective per-

sons in this State outside New York City. The county having the greatest number (784) is Monroe, and that having the largest percentage (0.0045) is Fulton. The census for this city is not yet complete.

A Missouri Health Society.—The Missouri State Board of Health has issued a call for a meeting of the Missouri Valley Health Association to be held in St. Joseph, November 27 to 28. The entire State is included in the call. All the commercial clubs, incorporated cities, and civic organizations will be asked to name delegates, the object being to launch a concentrated move for improving health conditions in all parts of the State and to secure general co-operation with this end in view.

Chicago Clinics.—The Committee on Medical Education of the Chicago Medical Society has requested all the hospitals of the city to hold stated free clinics open to medical and surgical practitioners of the United States, to publish a daily bulletin of such clinics under the auspices of the Chicago Medical Society, according to the plan followed for some time in New York, and to hold special medical and surgical courses outside of the free clinics.

Medical Society Elections.—South Texas District Medical Association.—At the annual meeting of this society, held in Galveston, October 10, the following officers were elected: *President*, Dr. M. F. Bledsoe of Port Arthur; *Vice-President*, Dr. A. E. Malsh of Victoria; *Secretary and Treasurer*, Dr. W. F. Thompson of Beaumont, re-elected. The next meeting will be held in Victoria.

Medical Society of Warren County, N. Y.—At the annual meeting of this society held October 14, the following officers were elected: *President*, Dr. LeRoy M. Haviland; *Vice-President*, Dr. Virgil D. Selleck; *Secretary and Treasurer*, Dr. C. R. Hoffman; *Board of Censors*, Dr. J. J. Montgomery of Luzerne, Dr. B. J. Singleton, Dr. Alex McKee; *Delegate to State Society*, Dr. H. E. Clarke; alternate, Dr. T. I. Henning; *Delegate to District Branch*, Dr. J. M. Griffin, alternate, Dr. Annetta E. Barber.

Fifth South Carolina District Medical Association.—An organization of this society was afforded on October 12, and it was decided to hold the initial meeting on November 3, in Rock Hill. The following officers were elected: *President*, Dr. E. W. Pressly of Clover; *First Vice-President*, Dr. Frank Ferguson of Gaffney; *Second Vice-President*, Dr. Samuel Lindsay of Winnsboro; *Secretary and Treasurer*, Dr. George A. Hennies of Chester.

Knox County (Ill.) Medical Society.—At the annual meeting of this society, held at Galesburg, October 16, the following officers were elected: *President*, Dr. G. A. Longbrake; *Vice-President*, Dr. R. J. Stewart; *Secretary*, Dr. G. S. Bower; *Censor*, Dr. G. S. Chalmers.

Obituary Notes.—Dr. Bukk G. Carleton of New York, a graduate of the New York Homeopathic Medical College and Hospital in 1876, genito-urinary surgeon to the Metropolitan, Hahnemann, and Flower Hospitals, and consulting surgeon to Grace Hospital, for several years professor of anatomy at the Homeopathic Medical College, and a member of the American Institute of Homeopathy, the Academy of Pathological Science, the Interstate Medical Society, and the New York State Homeopathic Medical Society, of which he was president in 1904, died at his home after a long illness, on October 20, aged 57 years.

Dr. Nicholas Z. Wagener of Sturgeon Bay, Wis., a graduate of the Northwestern University Medical School, Chicago, in 1904, a member of the State Medical Society of Wisconsin and the Door County Medical Society, and secretary of the latter, died suddenly on October 3, one week after an operation for appendicitis, aged forty-one years.

Dr. Joseph Singleton Shoemaker died at Philadelphia on October 7 at the age of fifty-one years. He was graduated from Hahnemann Medical College and Hospital in the class of 1888.

Dr. Arthur Scott Gilson of Portland, Me., a graduate of the Medical School of Maine, Portland, in 1894, and a member of the American Medical Association, the Maine Medical Association, and the Cumberland County Medical Society, died at his home, after a long illness, on October 9, aged fifty-nine years.

Dr. William James Lumsden of Elizabeth City, N. C., a graduate of the University of Maryland, School of Medicine, Baltimore, in 1869, a member of the American Medical Association, the Medical Society of the State of North Carolina, and the Pasquetauk-Camden-Dare Counties Medical Society, died at his home, from paralysis, on October 14, aged 68 years.

Dr. Daniel D. Neff of Syracuse, N. Y., a graduate of the Bellevue Hospital Medical College, New York, in 1894, died suddenly at his home on October 13, aged 45 years.

Dr. Eugene J. Hickey of Warren, Vt., a graduate of the University of Vermont, College of Medicine, Burlington, in 1907, and a member of the Vermont State and Washington County Medical Societies, died at his home on October 6, aged 32 years.

Dr. Claudius H. Morris of Galveston, Tex., a graduate of the Medical College of Indiana, Indianapolis, in 1881, died in San Antonio, after a long illness, on October 7, aged 61 years.

Dr. John W. Jones of Clinton, Wis., a graduate of the Eclectic Medical College of Cincinnati, Ohio, in 1868, died at the home of his daughter in Milton, Wis., on October 14, aged 80 years.

Dr. Frederick L. Davis of Biddeford, Me., a graduate of the Medical School of Maine, Portland, in 1888, a member of the Maine Medical Association and the York County Medical Society, and consulting physician to the Webber Hospital, of which he was one of the founders and a member of the board of directors, died suddenly at his home on October 10, aged 55 years.

Dr. Charles Jay Seltzer died of heart disease at Lebanon, Pa., on October 23 at the age of 58 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1881. Subsequently he served as resident physician in the Philadelphia Hospital and at a later date he was Laryngologist to the Hospital. He was for twenty years Assistant Surgeon to Wills Eye Hospital at Philadelphia.

Dr. William W. Johnson died at Chester, Pa., on October 21 at the age of 67 years as a result of heart disease. He was graduated from the medical department of the University of Pennsylvania in the class of 1865.

Dr. James Porter Brailler of Alexandria, Pa., a graduate of the Medico-Chirurgical College of Philadelphia in 1909, and a member of the American Medical Association, the Medical Society of the State of Pennsylvania, and the Huntingdon County Medical Society, was instantly killed in an automobile accident on October 18, aged 31 years.

Correspondence.

GONORRHEA, MARRIAGE, AND THE COMPLEMENT FIXATION TEST.

To the Editor of the Medical Record:

Sir:—Few responsibilities are greater than the one the physician is confronted with when he has to give a categorical answer to his once gonorrheal patient's question: "May I get married?" We know that in the terminal stages of all gonorrheas and all chronic cases which have no discharge, the microscopic examination gives us little of value. The field may be negative or it may contain cocci of doubtful morphological characteristics; and the answer given us by cultures is often just as unreliable, if not more so.

The venereal specialist therefore heaved a sigh of relief when the perfected complement fixation test became available. It is a very good and mostly reliable test—when positive, but when negative its value is much, very much slighter. We know that ten negative tests do not have the same value as one positive, and it is to emphasize the point and to warn the profession not to reach definite conclusions on the basis of laboratory tests *alone*, that these lines are penned. We have not a single laboratory test on whose findings alone, either positive or negative, but especially negative, I would be willing to make a diagnosis. In every disease we must consider the *tout ensemble;* it is only the history, the symptoms, the sequence of events, plus laboratory tests, that give us permission to make a definite diagnosis; and sometimes not even then.

A case was sent to me a month ago for final decision as to the permissibility or non-permissibility of getting married. A complement fixation test had been made and found negative, and his physician gave him permission to get married. The patient, however, himself noticing shreds in the urine, wanted to make doubly sure, and consulted me. No gonococci could be demonstrated, but as the shreds were numerous and could be found in the urine passed in as short a time as one hour after the previous urination, I said that I would advise caution and it would be preferable to delay the marriage for two or three months. Everything *might* be all right, I was not sure that any disastrous results would follow, but it would be taking a chance, I explained to him. With the first physician's positive permission and with my only tentative prohibition, the patient went and got married. And this morning, after three weeks of married life, he brought in his wife with a well developed gonorrheal cervicitis in which the gonococci are clearly demonstrable in great multitudes.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

THE NEW BRITISH PHARMACOPOEIA—THE ACCUMULATED FUND OF INSURED PERSONS—OPENING MEETINGS OF GENERAL MEDICAL SOCIETIES.

London, October 9, 1914.

The revised British Pharmacopeia for 1914 has been printed and copies may now be seen at the several offices of the General Medical Council (in London, Edinburgh and Dublin) and will remain there for inspection by those interested until the end of the year, when it will be officially published by statutory notices in the *Gazette* of December 31. Thus it will come into force on January 1, 1915, and be the only authorized codex until a further revision is made. It has been edited for the council by Professor Tirard of King's College and Professor Greenish of the Pharmaceutical Society, whose names inspire confidence and whose services are duly acknowledged in the preface.

Researches in pharmacy carried on since the last edition by the councils' committees and other authorities have been consulted as well as such criticisms as have been made upon them. The metric system of weights and measures has at length obtained resognition, but its triumph is not complete and its advocates will not be satisfied. It has been used for the analyses and pharmaceutical computations. But much more important is its extension to the doses of the remedies, though not absolutely. It is adopted as an alternative; the doses being stated in both systems in the expectation that the decimal will gradually come into use without too much inconvenience to prescribers who are further recommended to discard the common symbols for dram and ounce on the ground that they are too apt to be misread. These changes will affect dispensers as well as prescribers, more than general practitioners, though these also will have to consider them. The seniors in all classes will no doubt feel them most and indeed some grumblings are already heard about the nuisance inflicted by trivial alterations that for some time will intrude themselves into the fixing of every dose.

But there are alterations of dosage which are far from trivial, depending for the most part on changes in the strength of preparations. Tincture of opium is one-third stronger and considering the constancy of its use, extending to the public which will doubtless continue to buy and consume its laudanum, I think the danger of the alteration much greater than that of misreading the symbols for weights and measures. Another example is strophanthus, of which the tincture is quadrupled in strength, at any rate four times as much of the drug is to be used for the maceration. On the other hand, the proportion of nux vomica to be employed is reduced by half.

There are forty-three additional remedies in the revised British Pharmacopoeia. Among them I note acetone, aspirin, adrenalin, barbitone, cresol, guaiacol, hexamine, phenolphthalein, resorcin, trional, and several others and their compounds. The omissions are far more numerous, no less than 168 articles present in the last edition having been discarded. Some of these are in general use, such as scammony, gallic acid, sp. ætheris compositus, but their exclusion is not of much import as they can continue in use all the same and no doubt many will maintain their popularity for a longer time. Blisters will in future be made with cantharidin, which displaces the crude drug. In the same way coca, jaborandi, and physostigma make way for their active principles or salts of them.

The addendum of Indian and colonial medicaments disappears from the new edition, such articles as are retained taking their places in the body of the work.

Some alterations of patent compounds have been made to comply with recommendations of the International Conference (1902). Some, on the contrary, have not been so dealt with, the objection to

them being stated. The atomic weights adopted are those of the International Committee.

The word mil, which is officially recognized by the Board of Trade displaces cubic centimeter and so can be used in prescribing. It is a convenient abbreviation of millilitre, which is defined as the volume of 1 gram of water at 4° C. A decimil = 1.69 minims as nearly as may be and the centimil 0.169 minim.

The doses stated in the pharmocopeia are not authoritative and every practitioner is responsible for his employment of remedies. But dispensers are expected to satisfy themselves that a prescriber who orders an unusually large dose intends to do so. In such case many prescribers initial the line of the unusual amount and the pharmacopeia might very well have inserted a recommendation to make this precaution general.

The £90,000 accumulated in respect of insured persons who had not chosen or doctors for 1913 having been distributed among the practitioners on the panel settles the discussion that took place as to their right to this money. To many such an unexpected addition to their earnings was welcome enough. But to those not concerned in the matter the claim may seem a weak one and the consciousness that it is so may account for the heat with which it was sometimes urged. The money accumulated because the sick did not state what was to be done with fees which were to be paid as to cases which did not employ the panel doctor, these cases were very numerous. Those on the panel, or most of them, held that it should be distributed among them in accordance with the numbers on their lists. As there were no other claimants the objetcors were only some economists and persons who were shocked at the idea of men asking for fees they had not earned. The panel committee invited the recipients to subscribe towards a motor ambulance for the Red Cross Society as a thankoffering for their good fortune.

On Monday evening next the Medical Society of London will begin its 142d session with the annual general meeting at which Sir John Bland-Sutton, the incoming president, will deliver his address.

On the following Friday the demonstrations at the Royal College of Surgeons for practitioners and advanced students will be begun by Professor Arthur Keith, who will show specimens illustrating gunshot injuries of the head.

The excellent library of this society was founded by Dr. Lettsom in memory of whom is the course of Lettsomian lectures delivered annually. It contains a full collection of modern medical literature as well as numerous early works attractive to bibliophiles. There is a reprint of Seroetus on the Trinity from the one copy which escaped being burnt. Also the manuscript diary of Dr. John Ward of Stratford-on-Avon, a clergyman who practised medicine.

Nerve Deafness Associated with Anemia.—D. McKenzie reports the case of a woman aged 41 who complained of deafness and tinnitus of three months' duration. The hearing tests showed slight nerve deafness. The caloric test in both ears showed violent nystagmus in twenty seconds with extensive vertigo. The patient's evident anemia led to a blood examination, which resulted as follows: red cells, 4,000,000; white cells, 3,500. Differential count: leucocytes, 60 per cent.; lymphocytes, 40 per cent.; oxyphiles, 2.5 per cent.; red cells: poikilocytosis; no erythroblasts—*i.e.* anemia; leucopenia. The urine showed a trace of sugar but no albumin.—*Proceedings of the Royal Society of Medicine.*

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

FLOOD IN MANILA—PRECAUTIONS AGAINST EPIDEMIC DISEASE—SANITARY ADVANTAGES OF THE FLOOD.

MANILA, September 12, 1914.

DURING the past two weeks the matter of most medical interest has been the great flood which submerged Manila, the greatest in the memory of living man. It came as a climax of weeks of steady downpour resulting from a succession of typhoons with tremendous precipitation in Manila and the lake basin behind it. Only the walled city, a small part of the business district across the river, and a strip along the beach in Ermita escaped. In all other districts the water stood from one to four feet deep, and in certain parts of Santa Ana and Paco it was more. It was three feet deep around the Governor-General's palace at Malacanan.

Fortunately the currents were not swift and only a few lives were lost by drowning, but a rise of another foot would have resulted in many casualties. The police also worked very energetically, and, taking possession of canoes, boats, rafts, etc., they moved some twenty thousand people to places of safety. Schools, churches and other buildings were opened as temporary refuges. The Government also distributed free rations of rice, fish, salt, and condensed milk to needy persons, every police station and health station in the city serving as a distributing center. Fortunately at the end of two days the waters receded from most of the city and acute difficulties were thereby removed.

As flood anywhere is apt to be followed by epidemic, the health authorities promptly took precautionary measures, especially in view of the fact that a cholera infection was present in the city. Dr. E. L. Munson, lately appointed Acting Director of Health, on being interviewed by the papers, called attention to the fact that a certain increase in the sickness was to be expected. He asked that householders promptly clean their premises of the slime and refuse left by the receding waters, while the city authorities were taking similar action in the streets and parks. He called attention to the fact that the flood waters had risen so high as to submerge for days not only the sewer system water closets, but those equipped with pails, their filth mingling with the flood waters. The toilets in many private houses were also put out of use. The result was that for days a large part of the population necessarily disposed of its excreta by throwing it into the flood waters under and about their houses. A large part of the public hydrants were also submerged, cutting off all possibility in the poorer districts of procuring a pure water supply. Great numbers of people were thus forced to dip their water supply from the flood waters, fouled as they were with the filth and scourings of a great city. Nor could many of them render this water safe by boiling, from lack of fuel.

Food was short, as the poorer classes carry little if any supply in their homes, and many stores and booths were put out of business. Many had insufficient food, and that imperfectly prepared. A large part of the population was repeatedly drenched in the chilly flood waters and the incessant downpour, lack of fires, and insufficient change of clothing among the poor practically kept that class in wet garments for several days at a time. People also crowded into each others' houses or formed new large groups, with resulting increased

danger of transmitting infection from the many cholera carriers present. Persons sick or dead from infectious diseases were not promptly discovered by the sanitary inspectors, who with the disinfectors did much of their work in boats. All this disturbance, said Dr. Munson, would result in a rise in the intestinal and respiratory diseases and the infant and other general mortality. As a partial offset the city was receiving such a thorough cleansing as it had never before experienced. All surface filth and refuse were being washed away and the esteros were being thoroughly flushed and scoured out. Thousands of rats, especially litters of young, and the fleas infesting underground burrows and rat runs, would be drowned. The burrows would be silted up and adult rats escaping to upper floors would have to remain for some time with difficulties as to food supply and few places of refuge against their destruction. There would probably be a very great diminution in the rat population accordingly, though the plague of rats as a whole, from their becoming more conspicuous, would seem to increase.

Since the flood there has been quite a little rise in mortality along the lines just mentioned. The cholera cases were doubled for some days, though nothing amounting to the nature of an epidemic has been reached. The later cases have occurred particularly on the outskirts of the city, where public closets and water hydrants are less ready of access. There is much reason to suspect that many of these cases are due to the use of flood waters which have been retained in surface pools and depressions.

Progress of Medical Science.

5. Thyroid Operations under Local Anesthesia. F. H. Lahey.

2. A Theory of Cancer.—S. W. Little presents a theory the important points of which are as follows: Cancer is a disease of disordered nutrition. The probable origin of the growth is in highly specialized cells, which for some reason or other (possibly always trauma) have undergone a retrograde metamorphosis to the point where the power of reproduction, common originally to all cells but lost in these highly specialized cells, has reappeared. This reproduction of such reverted cells is caused by a relative hypofunction of certain ductless glands. To produce cancer such hypofunction must be primarily in a ductless gland derived from the same blastodermic layer as are the cells from which the cancer originates. For example, cancer of the breast implies hypofunction of some ductless gland or glands derived from the ectoderm—the breast epithelium being ectodermic in origin. In some vital manner sugar metabolism and calcium metabolism are involved in the disordered nutrition resulting in cancer. The ductless glands at fault in each case have some vital relation to sugar metabolism or calcium metabolism or both. As bearing on the last two points it has been shown that cancer patients in general have a hyperglycemia, though rarely a glycosuria. Diabetes and cancer are rarely present together. Cancer patients, like tuberculosis patients, have in general also a poor calcium metabolism, the "precancerous" condition resembling in many respects the "pretuberculous" condition.

3. Gunshot and Bayonet Wounds of the Stomach.—C. G. Cumston states that the usual damage done by the projectile within the abdomen is so extensive that death results at once. Logically it may well be argued that a laparotomy is indicated to control the dangers of intra-abdominal hemorrhage, and above all the effusion of the gastric and intestinal contents. This is what the majority of surgeons thought who were called into action in the South African war, and everything had been prepared for the treatment of abdominal wounds by immediate laparotomy. But the results of this practice quickly showed that the mortality of the operated cases was greater than of those patients treated by temporization, and the conclusion of all the great amount of matter that has been written on the subject is that a great number of those thus wounded die before they are removed from the field, that among those removed a number die from peritonitis, but that quite a large proportion recover without operation, and that almost all submitted to laparotomy die. Consequently, at the present time, opinion is unanimous that abstention is proper, and this is undoubtedly the correct view in the vast majority of cases, since the time required in carrying out these operations is pure loss and could be far more usefully employed in other injuries. There are cases which will die from internal hemorrhage if not immediately operated on, and this is the only indication for surgical interference in abdominal wounds on the battlefield. But since a laparotomy is undertaken for the control of the loss of blood, after this has been accomplished it is better perhaps to do a complete piece of work, since the abdomen is opened, and close gastric or intestinal perforations when present.

4. Practical Features Associated with the Treatment of Obscure Arthritis.—H. W. Marshall notes that the search for and discovery of new therapeutic agents undoubtedly will continue in the future as in the past, and out of many possibilities there will be found a few remedies probably that will be better than some we now have. Single specific measures, however, will never fill satisfactorily the need for comprehensive understanding of joint diseases. Increased success presumably will come to an important degree from closer cooperation between practitioners and specialists and plans that benefit all concerned, namely, the patients, family physicians, and the special workers. One important line of advance presumably will be through improving the possibilities of home treatments. Lack of appreciation of quantitative defects in therapeutic methods is a very important stumbling block in the path of progress that is overlooked because of its uninteresting and commonplace nature.

5. Thyroid Operations under Local Anesthesia.—F. H. Lahey describes his method of operating as follows: A freshly prepared 2 per cent. solution of novocain containing fifteen minims of adrenalin to the ounce is used. The first infiltration is made across the neck in the line of the proposed collar incision, and is more satisfactory in the writer's experience if made into the skin rather than in a large infiltration into the alveolar tissue beneath the skin. Through the plainly visible line of infiltration the skin incision is carried down to the platysma muscle. Care must now be taken in going through this muscle, as it contains a number of large and small veins, the clamping of which often produces a sharp twinge of pain. This is overcome for the most part by the injection of novocain around the larger veins before they are clamped. The incision across the neck now having reached the sternohyoid, sternothyroid, and mastoid muscles, an infiltration of the flap of

skin and platysma made by the curve of the horseshoe incision is effected by inserting the needle and injecting deeply between the platysma and the two underlying muscles. A little of the solution is now injected along the anterior borders of the two sternomastoids, which are then dissected free from their attachment to the sternohyoid. With no further infiltration a longitudinal incision may now be made in the median line through the sternohyoid and thyroid down to the anterior surface of the gland. This is enlarged upward to the upper attachment of the sternothyroid and downward to the sternal notch. By careful and gentle manipulation the sternothyroid on either side may now be freed from the anterior surface of the gland by sweeping the index finger beneath the muscles upward and downward, gradually farther and farther outward, until both sides are entirely clear. A few injections are necessary now across the sternohyoid and thyroid to overcome the very slight pain produced by closing the double set of clamps transversely on either side. Cutting between the clamps is productive of no pain whatever if done with a sharp knife and not with the scissors. The superior thyroids may next be caught between two clamps, and it has been the author's experience that, contrary to experiences with blood vessels in other regions, clamping of the vessels leading to the thyroid gland itself is productive of little or no pain. The removal of one lobe and its isthmus, and, if deemed wise, part of the other lobe, may then be proceeded with as with a general anesthetic. The thyroid itself has little sensitiveness, and the patient complains of no pain from manipulations of it except when it is dragged upon or crushed either with clamps or in locking double hooks, and then but slight pain. The portion of the thyroid to be removed having been taken out and the vessels tied, a little novocain is injected in the skin beneath the center of the collar incision and a pair of snaps is worked through a small incision until a drain can be caught in their jaws and withdrawn through the drain hole. The muscles—sternohyoid, thyroid, and plastysma—may now be sutured with no further infiltration, and likewise the skin sutured painlessly, even if the operation has consumed an hour in time.

10. Purpura Hemorrhagica Treated with Horse Serum. J. M. Bodenheimer.

4. Median Bar Obstruction in Prostatic Disease.—J. D. Whitall divides the treatment of this condition into: (1) medical—(a) local, (b) general; and (2) surgical. The medical treatment consists in the administration of an abundance of pure water and urinary antiseptics. If cystitis is marked, irrigation of the bladder must be practised twice daily till the condition is controlled. Constipation must be corrected. If the patient leads a catheter life, irritation and inflammation of the bladder can be kept down only by the most rigid surgical cleanliness and regard to instruments and solutions. The skin must be kept active. The diet must be modified; nothing like rich or highly seasoned foods or alcohol being permitted. A patient must be made comfortable for a number of months along these lines, or the condition may grow worse, the average man growing tired of the rigid routine laid down. The borderline between medical and surgical cases is not rigid, but one merges into the other gradually. If after several months' treatment, there is not much, if any improvement, and if the patient fails to live the catheter life properly, and provided, all things considered, he seems to present a fair risk, then surgical removal of the obstruction must be considered. Suprapubic prostatectomy provides the clearest and most rapid operative measure, and convalescence should be speedy. The entire gland with the obstructing isthmus is enucleated by blunt dissection with the index finger of the right hand, while the index finger of the left hand acts as a guide in the rectum. The entire prostatic urethra is removed with the isthmus. No retention catheter is used. A drainage tube of large caliber is passed through the incision and allowed to drain the urine for thirty-six to forty-eight hours. The bladder is irrigated twice daily with saline solution, and dressings are changed frequently. No urethral instrumentation is done. The patient is allowed to sit up out of bed by the seventh day.

5. Engineer and Alcohol.—T. D. Crothers states that a man on a locomotive or in charge of some machinery that requires constant care and judgment, may seem to be perfectly normal as long as everything goes on without a break or change, but let some unusual condition happen, some obstruction or breakdown, or some emergency which requires rapid and prompt judgment, and the defect will be seen. This is evident in men who are in positions where color signals are depended upon for guidance, as men in the pilot-house of a ship or on a locomotive on a dark night. After a glass or more of spirits, the color sense is impaired and cannot be depended upon, hence such men are very dangerous. The so-called moderate drinker is unfit for any such situation. Hearing is disturbed. The moderate drinker is unable to distinguish sounds with the same acuteness as before, and when they are heard it is after a longer lapse of time. Thus a whistle, the ticking of a clock, the sound of a bell is heard from a half second to three seconds later than by one who has had no alcohol.

9. Tropeolin as an Indicator for Gastric Acidity.—F. W. Rolph concludes that in the gastric contents of a normal individual, removed one hour after a test breakfast, there is no free hydrochloric acid. Toepfer's reagent is not solely a reagent for free hydrochloric acid, but will also react to certain highly ionized combinations of acid and protein and acid and aminoacid or peptide. As a measure of hyperacidity it is practically valueless. The acid which is sufficiently ionized to react to tropeolin is the acid which produces in some manner the symptoms of hyperacidity, and tropeolin can be used to measure that hyperacidity. The hydrochloric acid deficit to tropeolin is greatly raised in cancerous, compared to benign achylia.

3. Nervous and Mental Disturbances Following Castration in Women.—A. Gordon draws the following conclusions: Removal of the reproductive organs in women causes disturbances in the domain of the nervous system. These disturbances are of a purely functional nature. The disturbances are somatic and psychic. The psychic manifestations, while individually they belong to any of the varieties of psychoneuroses, nevertheless in their ensemble do not constitute any of the well-established classical forms of psychasthenia. True insanities are not observed. The generally observed symptoms are: restlessness with a tendency to move from place to place; difficulty of self-control; dissatisfaction with all and everything; difficulty in finding contentment in one's own efforts; want of interest in all absorbing subjects and objects; indifference, indolence, and pessimism. Sometimes there are outbreaks of anger with a tendency to attack. Among other symptoms may be mentioned: insomnia, gastrointestinal disturbances of a functional nature, headache, vague pains or paresthesias, also occasionally glycosuria; tendency to obesity is also observed in some patients. Individuals who presented various manifestations of psychoneuroses before they fell into the hands of surgeons, had their psychic phenomena decidedly aggravated after the uterus and ovaries or only ovaries were removed. As in the removed organs healthy portions of tissue were invariably found, it is to be supposed that the removal of the latter is in some relation to the morbid phenomena observed after the operations. The logical conclusion seems to be that one must be very cautious in advising operative procedures on the generative organs and the tendency should be to preserve as much as possible of any amount of normal tissues to be found in the uterus or ovaries. No operation, Gordon says, should be advised on healthy organs if a woman complains only of vague nervous disturbances.

4. Tuberous Sclerosis and Epilepsy.—N. S. Yawger points out the important rôle of heredity in the development of many cases of epilepsy. In some instances the cause is encephalitis dependent on the infectious diseases and sometimes it is traumatism, syphilis, or brain tumor. Occasionally epilepsy is observed to follow fright or other mental shock, but the manner of such influence one cannot understand except as it acts on an individual who is a potential epileptic. Another interesting group of cases are those reported as exhibiting a variety of attacks, at times even said to be major, minor, and psychic, which can in no wise be distinguished from those of epilepsy, but in which the attacks lessen or cease after the correction of some abnormal body condition as in intestinal intoxication. Tuberous sclerosis is the pathological basis of a few cases of epilepsy. The appearance presented by the unhardened tissue is that of markedly indurated areas of sclerosis which are slightly elevated beyond the surrounding brain substance; in addition there are sometimes found small tumors protruding into the ventricles. Tuberous sclerosis in connection with glial formation, Yawger says, may present the common picture of brain tumor.

5. A New Method of Treatment of Lupus Vulgaris.—M. L. Heidingsfeld details this method of treatment as follows: A saturated solution of trichloracetic acid is obtained by adding 10 drops of distilled water to an ounce of pure crystals. A tiny pledget of cotton is carefully wrapped around the end of a small rounded wooden toothpick, by means of which the remedy is applied as far as practicable to each congested nodule. The remedy apparently exerts a selective action, attacking the nodules with greater promptness and sparing somewhat the intervening more normal or cicatrized areas. This selective action is also noted if the remedy is applied more or less diffusely to a generally congested surface, although better results are usually obtained if it is carefully applied to the individual nodules for a few seconds at a time. The application produces a momentary sense of discomfort and stinging, which can be promptly allayed by the application of the following: Sulphurated potassa, zinc sulphate, of each, 1 part; zinc oxide, 10 parts; lime water, 15 parts; distilled water, enough to make, 40 parts; and powdered carmine, enough to color pink. This application serves, in addition to its protective and healing properties, as a cosmetic to hide the glaring whiteness produced for the time being by the trichloracetic acid. The trichloracetic acid should be applied to areas not much larger than a silver quarter, at a time, and repeated at seven to fourteen day intervals. Under the treatment the nodules become the seat of superficial crusts which exfoliate within from five to ten days. The general congestion diminishes, and the nodules lose in intensity of redness, and rapidly diminish in size, until they gradually become no larger than pin-heads and ultimately disappear. Mucous membrane lesions on the lips and within the nose have yielded with equal promptness and success.

8. Primary Carcinoma of the Lung.—B. M. Edlavitch emphasizes the fact that primary carcinoma of the lung as a distinct pathological and clinical entity is by no means as rare as it is generally thought to be. The group of symptoms that should be regarded with suspicion are progressive dyspnea, persistent cough, hemoptysis, pain, weakness and loss of weight, and pressure of metastatic effects. Signs of solidification of the lung, the presence of hemorrhagic pleural effusion, tachycardia without fever, and the absence of tubercle bacilli in the sputum are the significant objective findings. A diagnosis based on these clinical phenomena may be established by the use of the Röntgen rays, the bronchoscope or thoracotomy. Resection of the affected parts by radical operation should be attempted in every operable case. Radioactive emanations may prove to be of therapeutic value and, if possible, can be given a thorough trial whether surgery is resorted to or not.

7 A Note upon the Wounds of the Present Campaign. C. H. Makins.

1. **Pathology of Heart Function.**—T. Lewis discusses those disorders of the heart's action which are disturbances of the regular sequence of chamber contraction. The existence of auriculoventricular heart-block in man the subject of disease, has been abundantly proved; it has been proved in its many grades. The sequence of the contractions of auricle and ventricle is normally and wholly maintained through the medium of the auriculoventricular bundle; and structural damage which completely breaks this slender tract is responsible for a number of instances of complete dissociation. Experimental heart-block may be obtained in one of three chief ways: (1) by direct interference with the conducting tracts; (2) by stimulation of the vagus nerve, directly or indirectly; and (3) by the introduction of poisons into or by altering the metabolites of the circulating blood. Temporary heart-block in man, on the other hand, is to be explained on the grounds of nervous influence or chemical change in some instances. There are several disorders of the heart's action which are very closely related, namely, premature contractions (or extrasystoles) paroxysmal tachycardia, auricular flutter, and fibrillation. All these disturbances of the heart's action have the same essential pathology, whose simplest expression is the solitary premature contraction. The most remarkable character of the extrasystole is its prematurity. It occurs as a rule long before such time as a heart-beat is expected. The second distinctive character is the absence of rhythmic tendency. Those influences which promote spontaneous rhythms do not necessarily promote premature contractions. The reaction to the heart nerves is different in the two cases, and this has been noticed particularly in the case of the vagus. Stimulation of the vagus slows the physiological rhythm, be it of auricular or auriculoventricular origin; and with graded stimulation the slowing is gradual and is followed by an equally characteristic and gradual acceleration until the original rate is reached or surpassed. The action of the vagus upon extrasystolic beats, occurring successively, is essentially different. There is either no reaction or an abrupt and complete termination of these beats. The naturally rhythmic centers are not the centers from which extrasystoles commonly arise. The physiological rhythm is fastest which is propagated from tissues lying nearest to the superior cava, and as one passes to other centers the rhythmic properties are found to be less highly developed. These arguments support the proposition that certain of the preparatory processes which precede the normal contraction on the one hand, and the extrasystolic contraction on the other are essentially different, and that those which precede the latter are of a kind foreign to the physiological heart.

2. **Observations upon 31,000 Consecutive Medical Examinations.**—Sir John Collie presents a number of observations based upon 31,000 consecutive medical examinations made on behalf of two large public bodies and various insurance companies and solicitors during the past nine years. The proportion of candidates for the public service the author has had to reject has considerably increased. Up to 1911 the percentage of rejections was 9.9 per cent., but in the past three years the author has found it necessary to refuse 14.4 per cent. A large part of this increase is due to the number rejected on the ground of dental caries. It seems incredible that such a large number of people are ready to forfeit their chance of employment rather than undergo the treatment necessary to put their mouths into a proper condition. The following is a list of the causes of rejection of 1,423 cases: defective visual acuity, 479; dental caries, 254; heart disease, 110; albumin, 109; color blind, 103; hernia, 82; varicose veins, 54; disease of lungs, 25; poor physique, 22; syphilis, 18; various skin diseases, 16; diabetes, 13; varicocele, 11; debility, 10; deafness, 8; hydrocele, 8; refused physical examination, 7; obesity, 6; goiter, 6; hemorrhoids, 5; anemia, 5; alcohol, 4; gonorrhea, 4; mentally defective, 4; tuberculous spine, 3; deformity, 3; urethritis, 3; fainted at vaccination, 3; and various conditions of infrequent incidence, 48. The author urges the desirability of instituting a system of medical examination prior to employment. But he does not advocate the employment of only those who are physically perfect (the army of unemployed would be of enormous dimensions if that standard came into operation), and feels that in dealing with subsequent injuries or illnesses the advantage to be derived from a knowledge of pre-existing defects would be enormous. Furthermore, he says, if such medical examinations were made many men would not be permitted to undertake work the performance of which would be inviting disaster to themselves and others in their particular physical condition.

4. **The Transport of the Wounded in War.**—E. Kondoleon details the results of his experiences in the second Balkan war. He notes that for the transport of wounded men from the temporary stations to the central hospitals traveling by railway is often possible, in addition to which there are available bearers, motor-cars, ordinary carts, bullock carts, horses and mules, and the sanitary service wagons. A certain number of patients will be able to walk. Transport by bearers recruited locally would undoubtedly be the best of all, if it could be carried out everywhere and on a large scale. It is very comfortable for the wounded, who can rest quietly, even when being conveyed a long way, but unfortunately only a small number of wounded can be transported in this manner. It is therefore good to reserve this transport for the severest cases, in which an unsteady movement of any kind may prove fatal. Next come the motor-cars which are the best means of transport where there are carriage roads, because they secure both a quick and safe transport, although with some of them the occupants have to endure severe jolting. One of the ordinary transport motor-cars can easily hold ten wounded persons, so that if twenty or thirty such motor-cars are available 200 or 300 wounded can be conveyed every day to a great distance. These transport motor-cars were made use of from Cresna to Salonica and proved quite a success. For purposes of transport ordinary horse-carts and bullock carts must be replaced by motor-cars where possible. Transport by mules is useful in mountainous regions and when the immediate evacuation of a station becomes urgent. The ordinary transport carriages of the sanitary service are as a rule uncomfortable and the jolting of the wounded in them may be a cause of shock. It would be desirable if they could be replaced by transport motor-cars.

September 14, 1914.

Rôle of Contact Infection in the Spread of Cholera.—Wolter alludes to recently expressed beliefs in connection with cholera incidence in the Balkan war, that sudden explosions of the disease can only be explained by contact infection; but while one author assigns relatively small importance to this factor another regards it as of paramount significance. The fact that one body of troops may fall victim to the disease, while another close at hand may show no morbidity whatever from the same, naturally suggests contagion rather than local factors of time and space. But sharp local demarcation has always characterized the incidence of the cholera epidemics. Focal outbreaks appear to stand in relation to certain river valleys, and it has often been noted that after removal from certain localities the visitation ceases. The author cites many accounts of the recent epidemic appearance of cholera, and carefully avoids any reference to bacteriology. While drinking water epidemics are mentioned, there is hardly any consideration of the exact transmission of the disease. The latter, however, is grouped rather with typhoid and dysentery, than with typhus in which contact infection is the sole channel of transmission. Dealt with along old epidemiological lines the question of propagation lies between contact infection, fomites, and purely local conditions. The latter include soil, water, drainage, the weather, and other purely external factors. In the epidemic transmission of diseases the simple elements which explain sporadic transmission naturally fall short in accounting for the facts, just as they fail to explain the severity and mildness, and the self-limitation of epidemics.

Hypernephroma of the Base of the Tongue.—Coenen refers to the origin of Grawitz tumors—as he prefers to call them—from aberrant germs of adrenal tissue. A localization in the base of the tongue is extremely rare. The patient, a woman of 62, had noticed a swelling on the tongue for about a year which caused difficulty in swallowing. On inspection a mass as large as an English walnut was seen at the right side of the base of the tongue. No positive diagnosis was made, but cancer and gumma were excluded. The tumor was extirpated through the lower jaw, which was submitted to temporary resection. The entire operation was done under local anesthesia and patient was not even put to bed afterwards. She escaped pneumonia and made a good recovery. There was no evidence of hypernephroma of the kidneys or adrenals.

Treatment of Vesical Tumors with High-Frequency Currents.—Renner traces the evolution of this resource. Beginning with the use of the cold and hot snare—a method requiring the utmost dexterity—the results of which were by no means encouraging, the next step was made possible by the introduction into general surgery of fulguration and the sparkless electric knife. Beer of New York then applied to vesical tumors the method of high frequency desiccation, employing an Oudin apparatus for the purpose. The method is erroneously termed fulguration in some quarters. Beer's procedure came into extensive use in certain medical centers. The author, in common with other German colleagues substituted for Oudin's outfit a diathermy apparatus, applied with a definite intensity, the tumors being coagulated together with the site of origin. The author has now treated six cases. Beer recommends the method only for clinical papillomata and particularly in heading off relapses after primary resections, in which there can be no doubt as to the malignant nature of the growths. The three cases first mentioned were of this character. The other three had never been subjected to operation, and in fact were almost inoperable. Coagulation was used apparently as palliative and in the hope that the growths might be controlled, despite the assertion that no indication for its use is apparent from the results of others. Compared with the use of the snare the operation is easy of execution, and is also not very painful. The urethra should be anesthetized and rectal suppositories of codein employed.

Simultaneous Interruption of Pregnancy and Sterilization in Tuberculosis.—Kunreuther describes twelve cases in which this procedure was carried out in the Landau Gynecological Clinic at Berlin. Pregnancy is terminated by abdominal supravaginal high amputation of the uterus, leaving the adnexa, all ligated, behind. By means of a wedge-shaped excision, sufficient to include the intact ovum, as much as possible of the corpus is spared. The patients were all multiparæ from 26 to 40, pregnant two to five months. Most of them were lost to view after the operation but in four who were traced the average gain in weight was fifteen pounds, while the tuberculous process had become stationary.

September 8, 1914.

Experimental Proof of the Occurrence of Defensive Ferments.—Abderhalden recalls that but two years have elapsed since he first announced his discovery of the possibility of a serodiagnosis of pregnancy. The activity in this direction has in the meantime become tremendous. To understand the intimate nature of the seroreactions involved, we must bear in mind that the nutriment stands in no direct relationship with cellular activities, because of its complete disintegration in the intestinal tract. The substances which are borne by the blood stream to the cells are formed by synthesis in the intestinal wall and the blood itself is thereby constantly renewed by products native to the human body. More than a thousand experiments have shown that when alien substances do reach the blood the latter possesses the power—which is cognate with that of the intestine—to humanize or individualize. But while the intestine produces its results with preformed ferments, the blood is compelled to generate ferments for the occasion, which disintegrate the alien protein, etc., in the same manner as the said native enzymes of the digestive fluids. It is the presence of certain clearage products in the blood which proves the presence of the extemporized ferments. A subject of great interest, involving apparently some contradiction, refers to certain products of individual origin which are at the same time alien to the individual blood. Since such substances do exist, must they be pathological? This is hardly possible. The placenta is a normal structure which should be homologous to the maternal individual yet it contains albumin which behaves in the blood as alien matter, causing the genesis of ferments for its digestion. What is true of a temporary organ like the placenta could also be true of some of the stable organs, provided that the functions of the latter had become perverted. The ferments which spring into existence in the blood are themselves alien to the latter, and the period during which they may be studied is of uncertain duration. One of the incidental discoveries is the alien character of tumor protein which causes ferments to appear in the blood for its destruction. Aside from the question of tumor diagnosis which has been extensively studied we note here therapeutic posibilities. We already know that the blood serum of humor patients can exert a positive influence on tumor growth. At present the evidence

of the existence of defensive ferments is multiplied; we have the optical or polarization method, the dialysis procedure, the ultramicroscope, the interferometer, the biological tests, etc. However despite the eminently specific character of the reactions we are not yet clear as to the specificity of the ferments, for we know little of the specificity of its so-called substratum, or substance to which the ferment adheres.

Causes of Death in Aneurysm of the Aorta.—Pohrt takes up this subject where Baer left off in 1912. The latter studied the causes of death in 26 cases, in which there was no attempt to transcend this small number of results. Baer found that the majority of deaths had been due to perforation. The author now investigated the records of fifty cases of aortic aneurysm at the Hamburg-Eppendorf Hospital during 1908-1913, and of this number 47 were carefully analyzed. Rupture or perforation occurred in 24 per cent., which was also the figure for aortic insufficiency as a cause of death. In 18 per cent. the fatal result was due to compression of vital organs in the thorax (trachea 6, esophagus 2, pulmonary artery 1). In the same percentage do we find the deaths due to intercurrent diseases. The percentage of death from rupture, while agreeing closely with Baer's figure, is far lower than in some published reports, which place it as high as 60. It is evident that the aneurysm in itself is not a prolific cause of death, *i.e.* it does not as a rule so damage the circulation that failure of the latter results. Only in the case of cylindrical dilatation does the aneurysm act as a functional cause of death from insufficiency of the aorta.

Roasted Sawdust as a Wound Dressing.—Hammer states that he has used this substance as a wound dressing for several years and that it should be of great value in military surgery for the dressing of wounds with wide openings of entrance or exit. The roasting to which the sawdust is submitted is of sufficient degree to char it to some extent. The result is a dry, sterile, fine, hygroscopic, disinfectant powder of nominal cost, which does not crust upon the wound surfaces. It is packed firmly into the wounds, with gauze outside, and renewed every one or two days. The author recommends it chiefly for discharging and suppurating wounds as it possesses no advantages on dry or granulating surfaces. Even as simple a resource, however, is not to be absolutely free for the troops for the author, preserving silence as to the process of preparing his sawdust, announces that it will be marketed under a trademark name.

Rubber Sponge Compression as a Hemostatic.—Werner, in admitting that this resource is by no means new believes that it ought to be of great value in military surgery, especially for the production of hemostasis in shot wounds, and especially those made by shrapnel. The sponges having absorbed the blood are left as a dressing and their presence acts as a preventive of secondary hemorrhage. It may be of advantage to roll several sponges up tightly and tie them together. This resource should be of great value in the prevention of traumatic hematoma. The sponges are readily sterilized by wringing out in antiseptic solutions and good specimens will stand repeated boiling without injury.

Deutsche medizinische Wochenschrift.

September 10, 1914.

Rare Case of von Bechterew's Disease.—Hoene's patient was a man twenty-four years of age with good family and personal history. He was postponed for one year in his military service as not strong enough. After having been accepted he had served six months without sick report. He then took cold after a swim and began to complain of rheumatoid pains in the loins and left hip. After some weeks of treatment in the hospital for muscular rheumatism he resumed his duties. Aside from pallor, which evidently did not depend on anemia, he was free from finds. It is certain that at this period he had no rigidity, spinal or elsewhere. As his pallor persisted, despite normal blood count and 90 per cent. hemoglobin, he was excused from the maneuvers and given employment at his trade of joiner. He next developed a second attack of "rheumatism" and later a third, both requiring hospital treatment. He now underwent an examination by the author. The chest expansion was good, and there were no *x*-ray shadows. The only find was as before the striking pallor. Diagnosis of muscular rheumatism. Received hot baths, aspirin, and Blaud's pills. In about one month's time a distinct typhosis and fixation of the upper-middle dorsal vertebræ was manifested, which was sensitive to pressure, and not visible in a radiogram. Patient next began to show variable temperature rises and to lose weight and muscle tone. These symptoms along with his pallor constituted a cachectic state. Von Pirquet negative, chest sounds normal. He continued to waste until he was a mere skeleton. The physiological lumbar lordosis had gradually disappeared as the vertebral column underwent immobilization. Some movement was still possible in the cervical spine. The thorax had also become completely immobilized and all breathing was done with the diaphragm. Despite his plight the patient felt well. The entire condition had been evolved in six months time. All possible plans of treatment not absolutely contraindicated were tested with negative results. The prognosis is hopeless.

The Error in the Salvarsan Treatment of Syphilis.—Kromayer first gives the admitted facts in relation to mercury as an antisyphilitic: In the great majority of cases it removes the clinical symptoms of the disease with surprising promptness. When given intensively it cures 90 per cent. of syphilitics. Its administration is chronic—it must be given in doses so small that the organism is not damaged. He next appends the admitted facts about salvarsan: it removes the clinical symptoms of the disease just as does mercury, *i.e.* with surprising promptness and certainty. After one high dose and after several high doses in succession there may appear severe syphilitic relapses of a kind previously unobserved, and especially the so-called neurorecidive. Numerous deaths have followed its use, both immediately and after an interval. In order that the action of the two substances may be contrasted so as to bring out the best virtues of salvarsan and protect patients from its ill action, it is necessary, first, to give a treatment lasting for from 4 to 6 weeks and consisting of a total dose of old salvarsan of 2 to 3 gms. broken up into 10 or 15 single doses. The results of such a cure are at least as good as those of an intensive mercury cure of the same duration. The latter moreover is very apt to depress the organism and cause loss of weight, while the corresponding salvarsan treatment increases the weight, and the dreaded neurorecidive is seldom encountered. Salvarsan is positively contraindicated in diseases of the heart, bloodvessels, kidneys, liver, and brain, save in very minute initial dosage cautiously increased. By pursuing this plan, giving but two centigrams to begin with, the author has successfully treated syphilitic diseases of the heart, etc. The two medicaments may be alternated but not given as synergists. Two great and irremediable drawbacks will still remain as handicaps to the use of salvarsan, to wit: the need of intravenous exhibition and the high price.

Insurance Medicine.

Accident and Disease.—In the investigation of the injuries caused by accident, Dr. G. Grahamsley Howitt, Medical Officer to the Metropolitan Railway and Consulting Medical Officer Colonial Mutual Life Assurance Society, London, points out that quite frequently a combination of disease with accident is found. The question then arises as to what has happened, and the difficulties which occur are extremely troublesome. The history is often meagre or exaggerated, while material facts are suppressed. The majority of cases are unsatisfactory from a medical point of view, because it is almost impossible to obtain any after-history. Moreover, the circumstances under which examinations are made are not always of the best, and a solicitor's office, or the patient's one room, with little or no light, is not the place most suitable for a careful examination. These circumstances often make it difficult to arrive at a clear diagnosis, to separate the disease from the injury, to say whether there is any relationship between the two or not. Is the disease the cause of the accident, or the accident the cause of the disease? Is there any relationship at all? Sometimes also there are cases where it is doubtful whether there has been any injury. In others it is certain there has been none. Howitt considers that it is decidedly necessary to have a well-educated medical man to deal with these cases.

Among the cases which give most trouble are those affecting the nervous system, and of these the most difficult to deal with are those following head injuries, as often there are no objective signs of injury, only subjective symptoms, and one has to depend entirely on observation as to whether the complaints made are consistent with actual damage. The neuroses, the functional disorders of the nervous system, including neurasthenia and hysteria, present more difficulties than all the others put together. Occasionally traumatic pneumonia and pleurisy are found after accident, but Howitt considers these conditions are rare with the exception of the pleurisy which is sometimes found following fractured ribs. At times there is trouble with cases of kidney disease; the kidneys are said to have been injured, and are found to be diseased; a common occurrence being injury to the legs, where edema is present as the result of kidney trouble; or there is trouble from stone, which, as an instance cited, was said to have been displaced by accident. Cases do occur of heart disease complicating accident, but they are not common. There is a well-known case of sudden death which was found to be due to ruptured aneurysm, and in which it was held that the employers were liable, that death had arisen out of and in the course of the man's employment. The special senses may be affected by accident, blindness and deafness being produced as the result. Howitt suggests that eventually workers will be examined and graded according to their capabilities, and such complications of disease with accident will be largely prevented. This is done in large business concerns and in the Government services, and especial care should be taken on railways, where sudden illness of an employee or death might have very serious consequences to the passengers.—Life Assurance Medical Officers' Association, May 6, 1914.

The Effects of Alcohol and Tobacco on Life Expectancy.—Dr. T. D. Crothers says that there is no question about the evil effects of alcohol in large doses, used continuously or at intervals. The laboratory work has shown beyond doubt its paralyzing effects in doses from a half to an ounce; also that it has a special action on the vasomotor centers, deranging the circulation, and that it dehydrates cells and tissue. Cells exposed to one-tenth of one per cent. of alcohol become shrunken and changed in appearance. The granular matter, the dendrites, and the nerve terminals are eroded, and after a time become the seat of inflammation. New toxins are formed which still further complicate the protoplasmic growth and activities of the body. Tobacco does the same thing, only in a lesser degree. These facts are amply confirmed by comparative studies of alcohol and tobacco on cell growth in plants and animals, showing deterrent and degenerative physiological effects that are unmistakable. There can be only one conclusion from this, and that is that alcohol is the most subtle and dangerous of all drugs, impairing health and lessening longevity. Examinations to determine these facts cannot be made satisfactory if limited to physical conditions. They must extend to the mental activities as well. Policyholders today are subjected to strains unknown a half a century ago. There are certain occupations, certain environments, that strongly predispose to the use of narcotics like alcohol and tobacco. There are certain causes, some of them psychical, that should be the subject of distinct and exhaustive examinations. Medical examiners should be laboratory and clinical judges for the deductive and inductive studies of the entire phenomena of living. They should have the largest liberty and greatest encouragement to include in these studies every possible physiological, psychological, and sociological question that enters into everyday life. If the companies are unable to limit their business to total abstainers there are already data sufficient to indicate the possibility of insuring moderate drinkers on a practical commercial basis; thus a man at forty who claims to be drinking alcohol in moderation should be rated with the same expectancy as a man of fifty or fifty-five, and pay premiums accordingly. A periodic drinker of thirty should be charged the same as one of forty-five or fifty. This is on the supposition that they are free from the ordinary symptoms of physical disability. The central fact is that the drink and drug taker has discounted the future and is prematurely aged, and the company can estimate this premature aging and issue policies accordingly. Persons acknowledging the moderate or occasional use of spirits should pay the same premium as persons from ten to twenty years older, depending on circumstances and conditions. The present system of making all classes pay the same rates is an injustice to the abstainer, who must pay for the increased risks which the company assumes by insuring the moderate drinker. Life insurance is a commercial business, without sentiment, and should recognize the changing conditions and discoveries in science as well as in business. The insurance companies must consider these facts on the same basis that railroad companies and large corporations do, who employ thousands of men, and demand the most exact work and highest efficiency which can come only from total abstainers. The medical examiner is the authority to protect the interests and prevent the inevitable losses which follow from neglect to recognize the teachings of science in this field of work.—American Life Convention, March, 1914.

Book Reviews.

DISEASES OF THE RECTUM AND COLON AND THEIR SURGICAL TREATMENT. By JEROME M. LYNCH, M.D., Professor of Rectal and Intestinal Surgery, New York Polyclinic; Attending Surgeon, Cornell Dispensary; Attending Proctologist, St. Mary's Hospital, Hoboken, N. J.; Attending Surgeon, Red Cross Hospital, New York; Consulting Proctologist, Nassau Hospital, Mineola, L. I.; Consulting Surgeon, New Jersey State Hospital; Assistant Surgeon, Medical Reserve, United States Navy; Fellow American Proctological Society, New York Gastroenterological Society, Northwestern Medical and Surgical Society, etc. Illustrated with 228 engravings and 9 colored plates. Philadelphia and New York: Lea & Febiger, 1914.

THIS is one of the best of the many recent textbooks on the diseases of the rectum and colon, a subject that has practically outlived the stepmotherly care of the general surgeon and has been raised to a dignified and useful specialty. This book has been written not only for those whose work is confined to rectal diseases, but also for the general practitioner. It is comprehensive in its scope and minute in the description of details that are often taken for granted and neglected. An idea of the thoroughness with which the subject is handled may be gained by a review of the chapter headings which are as follows: Examination and diagnosis, preparation of the patient for operation, anesthesia, embryology and malformations of the rectum and colon, hemorrhoids, fissure of the anus, ulceration of the rectum and anus, abscesses of the rectum and anus, fistula, pruritus ani, cryptitis and papillitis, stricture of the rectum and colon, prolapse of the rectum, venereal diseases of the anus and rectum, rupture, injuries, and wounds of the rectum, the colon, maldevelopment of the colon, dysentery, colitis, diverticula and diverticulitis, pigmentation of the bowel, intussusception, constipation, autointoxication, colostomy and ileostomy, appendicostomy, benign tumors, malignant tumors, short circuiting, foreign bodies in the rectum and colon, serums and vaccines, and *x*-ray examination of the intestine. The up-to-date character of this work is indicated in the chapter on cryptitis and papillitis, conditions which are responsible for a large number of cases of pruritus ani. The wide possibilities of the use of serums and vaccines in rectal therapy are carefully detailed. The book is well written and illustrated, and will be of service to the student, general practitioner, and rectal specialist.

COMPENDIUM DER ARZNEIMITTELLEHRE MIT BESONDERER BERÜCKSICHTIGUNG DER NEUEN ARZNEIMITTEL, DER ORGANOTHERAPIE, SEROLOGIE UND NÄHRPRAPARATE. Von DR. LIPOWSKI, Chefarzt der inneren Abteilung der Städtischen Diakonissenanstalt in Bromberg. Price, 5 marks. Berlin and Wien: Urban and Schwarzenberg; New York, Rebman Company, 1914.

THIS book is a compendium of materia medica, particularly of the newer remedies, organotherapy, serology, and nutrient preparations. It is compact but comprehensive and should prove valuable to the physician who would be guided through the mazes of the vast number of therapeutic agents that have been introduced within recent years.

A TEXT-BOOK OF MEDICAL DIAGNOSIS. By JAMES M. ANDERS, M.D., Ph.D., LL.D.; Professor of the Theory and Practice of Medicine and of Clinical Medicine, Medico-Chirurgical College of Philadelphia; Officier de l'Instruction Publique, etc., etc., and L. NAPOLEON BOSTON, A.M., M.D., Professor of Physical Diagnosis, Medico-Chirurgical College; Physician to the Philadelphia General Hospital; Pathologist to the Frankford Hospital. Second Edition. Thoroughly Revised, with 500 Illustrations, some of them in colors. Price $7.50 net. Philadelphia and London: W. B. Saunders Company, 1914.

THE present edition of this work maintains the high standard of the former edition in its thoroughness and practical value. It contains, besides, the following new matter: Movements of the two halves of the chest; electrocardiograms; extrasystole; auricular fibrillation; sinus irregularity; succussion sounds audible over the abdomen; abdominal tension with original methods of determination; albuminous sputum; cobra-venom reaction in syphilis; the tick in transmitting relapsing fever; the Rumpell-Leede phenomenon in scarlet fever (not the "Rumpell Leed phenomena" as given in the preface though correctly referred to in the text); inclusion bodies of Döhle in scarlet fever; sweating and its significance; *Trichinella spiralis* in the blood; MacEwen's sign and Brudzinski's sign (not "Brudzendski's sign" as given in the text and preface) of epidemic meningitis; Prendergast's reaction for typhoid fever; fatty emboli; pupillary reaction; drug eruptions; nitrogen content of the blood; respiratory movements in hiccough; colloidal nitrogen of the urine, and initial eruptions in measles. Clinical tables have been added on the following subjects: Bloody sputum; dyspnea; hemorrhage from the mouth; abdominal enlargement; vomiting; ascites; splenic enlargement; hematuria, and bacteriuria. Among the subjects that have been rewritten are Stokes-Adams disease; blood-pressure; ulceration of the duodenum; Addison's disease, and anterior poliomyelitis. The book is eminently practical and well written, with remarkably few errors, considering its size and comprehensiveness. It is profusely illustrated.

TEXTBOOK OF LOCAL ANESTHESIA FOR STUDENTS AND PRACTITIONERS. By Prof. Dr. GEORG HIRSCHEL, Heidelberg, 1. Assistant in the Surgical Clinic. With an introductory preface by Prof. Dr. WILMS. Translated by RONALD E. S. KROHN, M.D., London. 181 pages, with 103 illustrations in the text. Price, cloth, $2.75 net. New York: William Wood & Company, 1914.

LOCAL and regional anesthesia, considered of such limited application even a decade ago that most of the larger surgeries of that period dismissed the subject, as far as general surgery was concerned, with a few lines or paragraphs, has been developed to such an extent in recent years that almost a new era in the practice of surgery may be said to have arisen. German and American surgeons have been foremost in the development of this method, and many important books on this subject have recently appeared. Among these, that of Hirschel deserves a place in the front rank.

Beginning with a brief survey of the history of local anesthesia, the indications and contraindications for its use, the drugs, solutions, and armamentarium required, the author rapidly passes to the discussion of its application to the special regions of the body. The technique of injection in the various regions is very clearly described and most effectively illustrated. To apply conduction anesthesia, a thorough knowledge of the course and relations of the various nerve trunks and their principal branches is absolutely essential. To this end many illustrations from truly remarkable dissections have been employed, some apparently original and many borrowed from Spalteholz's Atlas, Corning, and other authors. Other illustrations show surface form with tracings of the subjacent nerves, while the points of injection and the directions in which the needle is to be pushed are marked by dots and arrows, and the resulting anesthetic area often indicated.

While much further research will be necessary before a final accounting can be made of the value and limitations of local anesthesia in all its various phases, Hirschel's work cannot fail to impress one with the fact that the method already has a very large field of application, and encourage the hope of still greater future development, while it is an eminently practical guide for those desiring to employ local anesthesia in what seem, at the present time, to be suitable cases.

BEITRÄGE ZUR KLINIK DER INFEKTIONSKRANKHEITEN UND ZUR IMMUNITÄTSFORSCHUNG (MIT AUSSCHLUSS DER TUBERKULOSE) KLINISCHE BEITRÄGE. Herausgegeben von Prof. Dr. L. BRAUER, ärztlichem Direktor des Allgemeinen Krankenhauses Hamburg-Eppendorf. Redaktion: für die Originale; Dr. H. SCHOTTMÜLLER (klinischer und bakteriologischer Teil) und Dr. H. MUCH (Immunitätsweissenschaftlicher Teil), beide am Allgemeinen-Krankenhaus Hamburg-Eppendorf; für die Ergebnisse: Prof. Dr. H. LÜDKE, in Würzburg. 11 Band, 3. Heft. Price 6 marks. Würzburg: Curt Kabitzsch, 1914.

THE articles in this number comprise the following: A Contribution to the Clinical Study of Asiatic Cholera, by O. Hesse; The Significance of Bacteriological Controls, Before, During, and After Gynecological Operations, by A. Bauereisen; The Question of the Repeated Injections of a Curative Serum in Human Beings, by W. N. Klimenko; Diphtheria Bacillus Carriers, by H. Deist; the Foundation of Serodiagnosis and Chemotherapy in Syphilis, by P. von Szily, and Infection and Diabetes, by C. Funck. There can be no question as to the important field which this publication occupies in the presentation of the scientific and practical aspects of the infectious diseases.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF NEW YORK, FIRST DISTRICT BRANCH.

Eighth Annual Meeting, Held in New York City, October 8, 1914.

THE PRESIDENT, DR. HENRY LYLE WINTER OF CORNWALL, IN THE CHAIR.

(Special Report to the MEDICAL RECORD.)

President's Address.—Dr. HENRY LYLE WINTER of Cornwall said that instead of delivering the usual address he proposed to present briefly a few clinical facts which he had collected bearing on the "Late Cerebrospinal Manifestations of Inherited Syphilis." His reason for making this presentation was a failure to find in the literature any reference to the class of patients to which he wished to call attention. The finding of this group of cases was entirely accidental. Whenever possible he made it a routine practice to have the Wassermann test or Noguchi's modification of it made in all cerebrospinal cases. The first patient to which the speaker referred was a woman, sixty-one years of age, who had suffered from epileptoid seizures for three years. In this instance the Wassermann reaction was positive. At about the same time a sister, sixty-six years of age, presented herself, giving a history of recent slight hemiplegia. Because of the findings in the first case the Wassermann test was made and a positive result obtained. These cases were examined in July and August, 1911. In neither instance was it possible to obtain a history of acquired syphilis. This, together with the relationship of the patients, made the diagnosis of inherited syphilis reasonably certain. The interesting feature was that neither of these patients had given any clinical evidence of the existing disease until about sixty years of age. This suggested that other patients of advanced age and varying neurological conditions might give similar findings, and in following this line of inquiry twenty-four other patients had come under his observation, ranging from fifty-two to sixty-six years of age. They belonged to the general class of arteriosclerotics, with high blood pressures. The blood pressures varied from 152 to 280 mm. Some of the urines showed evidences of contracted kidneys. Of this series of patients six were hemiplegics; two had epileptoid seizures; five complained of vertigo with headache, of which two showed wild mental disturbances; one had facial neuralgia with rheumatism; one medial nerve neuritis; one multiple neuritis, and three were difficult to classify, but presented symptoms of gait, posture, etc., incident to senility. There was one case each of epileptic seizures of the Jacksonian type, aphasia, senile dementia, and paralysis agitans. The Wassermann reaction was positive in ten of the twenty-four cases. There were no symptoms by which one could differentiate between the syphilitic and the non-syphilitic groups, but positive reactions had been found where they were least expected. It would be impossible to say after a detailed study which of these patients suffered from hereditary syphilis and which did not. There was, however, a difference in the results obtained from treatment. The iodides were given in all the cases. Some of the results were startling, the syphilitic group showing greater and more prompt improvement than the others. The results of active mercurial treatment of the syphilitic group were *nil*. Salvarsan was used in only one instance and the marked prostration and bladder irritation made him timid about trying it in other cases. There was no apparent improvement from this single injection. The facts of interest in connection with this series of cases was that a person might go through life carrying inherited syphilis and never give any evidence of it until fifty-seven years of age, and that there were a certain number of cases of this type. They made it imperative that the possibilities should not be overlooked in any examination. Advanced age with an apparently clean history was no reason for omitting an examination of the blood. A second point of interest was that for years they had been meeting a class of cases more or less loosely designated arteriosclerosis and for these they had been taught that the iodides were the only medication needed. Some had improved under this treatment, but the majority of their cases had not turned out well. With the Wassermann examination as a routine the reason for the positive or negative results of the iodide treatment was very evident. The syphilities improved; the others did not, or at least comparatively slightly. The question as to why there were no results from the mercurial treatment Dr. Winter said he could not answer. It might have been because the lesions were of such a chronic character or that the courses of treatment were too short.

Obscure Causes of Disease.—Dr. W. STANTON GLEASON of Newburgh presented this paper, in which he considered the effects of the intestinal poisons and the by-products of defective metabolism. He stated that our present day knowledge of the toxic products, their influence on the cell, and the general disturbance of the proper correlation of organs was due to the effective conjoined work of the clinician and the laboratory worker. The understanding of one of the most prominent obscure causes of disease was based on the knowledge of protein digestion. Dr. Gleason reviewed the results of the investigations of Kutscher, Abderhalden, Mendel, Vaughn, Eastman, Mellanby and Eppinger, Runneford and Heyde, and Armstrong in relation to protein digestion and the part played by the large intestine. The general practitioner and the surgeon were alike impressed that a survey of the systemic consequences from infection originating in the large intestine forced on one a new viewpoint in medicine and surgery. Any defect in the large intestine, be it either mechanical or a fault in its function, resulted in a varied flora of bacteria within its walls. These microorganisms were of the anaerobic putrefactive type and acting on protein bodies produced toxic substances such as indol, skatol, and paracresol. These poisons being reabsorbed in the blood caused serious disturbance in the digestive, circulatory and nervous systems, and also a general irritation of the harmony of action of all the organs of the body. Armstrong held that within the past one hundred years the flesh intake of man had increased four times, and it was distinctly pointed out that the proximal end of the large intestine was only favorable to digesting vegetable substances. Therefore it was only a fair supposition that meat substances would naturally provoke indigestion with toxic products if conditions were not absolutely normal in the colon. Experimental studies from the Pasteur Institute showed premature senile changes induced in animals by the daily feeding of some of the indol, phenol, or paracresol compounds. These changes were strikingly similar to the pathological changes common to the aged. Focal infection was closely allied with local and general disease and frequently bore an important influence to the general well being of the individual from the difficulty of locating the source of its activity. Focal infection was essentially an obscure cause of disease. Usually its origin was in the head in the form of an alveolar abscess, tonsillar abscess, poor teeth, and various chronic sinus conditions. It might also come from appendicitis, salpingitis, prostatitis, etc. Acute rheumatic fever was considered by Rosenow of focal origin. Billings considered focal infection as largely responsible for arthritis, cholecystitis, pancreatitis, etc., and also held that when the defenses of the body were depressed by overwork or exposure, the individual was especially susceptible to focal infection. In investigating for obscure causes of disease the importance of the recognition of the focus of infection must be prominent in the physician's mind. Dr. Charles G. Kerley in an article as yet unpublished on "Disorders in Children Arising from Derangement of Function" brought out very clearly an obscure incipient cause of disease in children. He pointed out that during the period of rapid growth the metabolic processes were most active and that this was the time when they were apt to have metabolic defects in the utilization of complex foods. Faulty deposition of salts probably produced rachitis in children. Protein was rarely a disturbing factor in the diseases of childhood, but milk, butter, and especially sugar, might cause trouble. It was well assured that nearly every healthy child of well-to-do parents received two or three times as much energy food as was required. In case of defective metabolism of hydrocarbon, toxic products were formed which produced periodic disorders of function such as recurrent colds, recurrent noninfectious bronchitis, with or without asthma, recurrent vomiting, recurrent fever, and eczema, and so-called bilious attacks with or without vomiting. The treatment for this class of cases was to cut off sugar, and, if the case promised to be difficult, cow's milk was omitted from the diet. The carbo-

hydrates and fats found in vegetables, cereals, breadstuffs, and meats supplied all the heat and energy required. As to the lithemic type, they were given internal treatment of soda alone or combined with the salicylates. Another obscure cause of disease was found in uric acid. Investigators were still far from unanimous as to the origin of uric acid in the system, but it was known that a moderate amount of uric acid was essential to health; an overproduction was abnormal, and a menace to the human body. This excess was found in those individuals who had abnormally small lungs. In these cases it was difficult to reduce the overproduction by the usual methods of diet and régime. A second class of cases were those who persistently overindulged in foods rich in starches, sugars, and fats, and possibly proteins. Uric acid excess from any source was important, and its persistence if unchecked could not help but be an ever increasing menace to the integrity of the organs and an irritant to the nervous system. It was a reasonable argument to consider that the basic factors in arteriosclerosis and gradually rising blood pressure were due to systemic toxins probably from the colon and also from defective metabolism. Appreciating their limitations they strove to eliminate these toxins and often with pleasing results, especially when the increased blood pressure was not associated wtih kidney lesion. Such conditions as excess of uric acid and intestinal poisoning should be placed under the same general plan of treatment as had been suggested for the treatment of focal causes of disease and metabolic disturbances in children. Drawing our deductions from our present light of knowledge in the behavior of proteins as being a fertile source of systemic infection, and as L. F. Bishop stated, "We must not disregard the teachings of the chemistry of our bodies," therefore, the protein intake should be limited absolutely to body requirements or even less, for it was known that living protein tissue could be built up by both protein and carbohydrate elements. It was immaterial to the body growth whether the seroalbumin proteins came from plant or animal life. The carbohydrates were freely permissible except limiting the use of sugar and sugar combinations. Cheese was a safe substitute for the more potent proteins. Fruit acids were generally advantageous. The too free use of water was often a detriment as the surplus might cause overdistention of the colon. In arteriosclerosis an overabsorption of water threw an extra burden on the already embarrassed circulation. Little medicine should be used in these cases, but a proper regulation of diet, rest, and exercise should be suited to the individual patient.

Dr. Charles Gilmore Kerley of New York said that this type of paper was most timely. He referred to the work that was being done in physiological chemistry in the effort to elucidate some of these problems of metabolism. The clinician must work out the practical side of these problems as well as possible and tell what could be demonstrated clinically and then the laboratory worker should attempt to furnish the explanation. What had been said in regard to focal infection was true. The importance of focal infection, especially in the ears of children suffering from malnutrition, was not sufficiently appreciated. In the Babies' Hospital, during the summer, in certain cases a sudden cessation of growth had been noted attended by no evidence of illness or fever and in nearly every one of these cases some reason was found outside the intestinal tract. Attention had been centered too much on the digestive tract to the exclusion of other things, and it was well to bear in mind the possibility of a bacteriemia from some other source in children suffering from malnutrition. Much of the work that the physician was called upon to do did not relate to disease but to disorder of function. Frequently there was no pathology and yet the child was sick and after treating many such cases, studying them, and consulting with the mothers one came to group them. There might be no lesion, no pathology, and no dietetic error sufficient to account for them, yet it would be found that there was an excess of carbohydrate, especially in the form of sugar or a poor carbohydrate metabolism. In such instances toxins were produced about which the laboratory told them but little. Dr. Kerley reviewed the conditions, such as cyclic vomiting, recurrent bronchitis, with or without asthma, recurrent colds, and attacks simulating grip, biliousness, etc., that were due to an excessive carbohydrate intake, especially sugar, or to defective carbohydrate metabolism, and that could in many instances be controlled by a proper regulation of the diet and attention to hygiene. Lithemic children, the offspring of the well-to-do sedentary classes were particularly susceptible to this class of affections. In connection with the work of Mendel on fat oxidation, the speaker called attention to the observation that rabbits fed on butter fat grew and thrived, while those fed on lard did not, as they were unable to metabolize the fat in the form of lard. It was on such problems as this that the work of the laboratory men was needed and thus far they knew very little from the laboratory standpoint.

Dr. Floyd M. Crandall of New York remarked that years ago it was taught that the colon was simply a storage reservoir and that it did not make much difference if it was filled, but that now the part played by the colon in toxemia was well recognized. It was now well understood that these toxemias were due to infection from the colon, especially from fecal impaction in the cecal end. Surgeons felt that Lane had taken a rather extreme position on this subject when he held that the colon could as well be entirely dispensed with; most of them believed that operation if necessary was sufficient if limited to the cecum. A paper which he had listened to the previous evening had emphasized the importance of the cecum as the point of entrance of infection, not only in children but in adults. Another point of interest was that one source of nervousness, restlessness, and discomfort in children was uric acid. There was a type of children with a hereditary tendency to uric acid in which correcting the digestive function did not seem to give relief. In such cases, in addition to the dietetic treatment, salicylates of soda in small amounts might be given, as was sometimes done with cod liver oil, for a few days at the beginning of each month.

Dr. S. W. S. Toms of Nyack, N. Y., said that there was one point of interest that he had been observing for many years and that was that with colds and pyrexia that could not be accounted for an examination of the ears often showed an acute otitis, lasting for a few days and then clearing up after spontaneous rupture of the drum or paracentesis. In children under one or two years of age the stools might become offensive and green, due, in his opinion, directly to the otitis, the pus going down the throat. An infection of the tonsils might cause the same condition. Since his own child, some ten years ago, had nearly lost his life through failure on the part of his attendants to recognize an otitis, he had made it a routine practice to examine every child's ears.

Dr. Thomas F. Goodwin of Mount Vernon said that William H. Porter, in 1889, had written a series of articles on the suboxidation diseases and intestinal indigestion, and it agreed in general with the things they were now hearing, but physicians were just waking up to it. It was of interest that many of the so-called rheumatic conditions were due to intestinal toxemia. He referred to the significance of indican in the urine in this connection. One kind of focal infection sometimes overlooked was infection of the kidney due to the colon bacilli. If one could not find indican in the urine it was advisable in cases of this class to make a blood culture and one might find a streptococcus infection.

Address by President of the State Society.—Dr. George W. Wende of Buffalo spoke of the importance of the work of the State society, and pointed out the ways in which the society had worked for the welfare of the medical profession and of the public at large. He reviewed the part that it had taken in public health legislation, in codifying the rules of medical ethics and shaping medical practice laws, in suppressing irregular practitioners, and in protecting its own members in medical malpractice suits. He called to mind the work that the society had done in preventing the passage of antivivisection laws and of bills licensing osteopaths, mental healers, and chiropractics. He then urged physicians to assume the aggressive and to elect assemblymen who would protect the interests of physicians and of the public in the legislature. He urged upon all eligible physicians the duty of affiliating themselves with their county and State society. In Norway 95 per cent. of physicians belonged to the national organization while in New York County only 46 per cent. were affiliated with their county society. This was difficult to explain in a great medical center such as New York. Dr. Wende announced that the State Society had formed a new section, the Section on Syphilis, and explained that this had been done not only to give an opportunity for the study of a disease which was of such vital importance, but also for the purpose of impress-

ing on the profession and the public that this was a disease not necessarily of the low and the vile but one which might affect the most innocent, the most normal, and the most intelligent in the community.

Toxic Diseases of the Nervous System.—Dr. EDWARD D. FISHER of New York read this paper, stating that his object in introducing this subject was to bring into consideration the large number of cases which came under the observation of every physician of diseases of the nervous system, which, both in diagnosis and treatment, were indefinite and unsatisfactory. He said he referred to those cases which did not fall under the recognized forms of cerebral and spinal disease such as cerebrospinal meningitis, poliomyelitis, diphtheria, or tetanus, but which were serious in their manifestations, and which he believed belonged to the same class as the above mentioned diseases and were also of bacteriological origin, though of an unknown nature. Toxins were given off which affected the cells of the nervous system causing impairment or destruction of the nerves. Dr. Fisher believed that they had to deal with many germ diseases and their accompanying toxins which as yet remained unclassified, but which resembled the better known infectious diseases in every respect. After pointing out the difference between bacterial and toxic agents, Dr. Fisher called attention to the fact that the toxic action of bacterial or other toxins was dependent on the chemical union of the toxin with the cells of the body, and that the nervous system was especially susceptible to this assimilation. They knew that it was the toxin rather than the microbe itself which caused the clinical manifestations. This was well demonstrated in diphtheria and tetanus. The dead bacilli introduced into the system produced all the symptoms of the disease, showing that it was the end product, the sterile chemical solution, which caused the cellular changes. Syphilis was an excellent illustration of this view. The spirochetes remained active and were demonstrable only in the early stages of the disease, but in the later manifestations, as in tabes and general paresis, it was not the direct action of the living organism which caused the symptomatology, but the chemical poison thrown out by the syphilitic germ. In the present treatment of this disease they probably did not succeed in killing the active agent, they simply controlled its multiplication, leaving it ever ready when the controlling influence was removed to take on an active increase. The same was true in malaria. Quinine did not kill the plasmodium, it only controlled its development. The influenza infection demonstrated the effect of a toxin on the nervous system. Its manifold symptoms were in disease of the meninges, the brain, and the cord. Involvement of the anterior horns, a form of poliomyelitis not dependent on the specific organism, had been discovered by Flexner. Influenza seemed to represent the indefinite class of toxic diseases. They had now a rather complete knowledge of the specific germs in cerebrospinal meningitis and in poliomyelitis. It was still unknown for myelitis and Landry's paralysis. They both presented clinical pictures which suggested a distinct poison, microbic or toxic in character. They had all observed cases which did not fall completely into any of the classes clinically and a few such cases had come under his observation.

The first case was one of Landry's paralysis which was observed from its beginning and followed to its fatal termination. An autopsy was fortunately obtained. In the literature of this subject various lesions of the nervous system had been recorded, affecting the peripheral nerves, the spinal cord, the medulla, and the brain. In this case there was an ascending paralysis, with attending neuritis, which followed the usual course of extension, later involving the upper extremities and the bulbar nerves, resulting in respiratory failure. The pathological findings were definite, involving both the peripheral and central nervous system. The course of the disease was longer than that usually described, extending over six weeks, but otherwise the case was typical in its manifestations. The second case was that of a female, 28 years of age, whose previous history was negative. She complained of pain in the left side of the chest, high temperature, severe headache, vomiting, rigidity of the neck, a few days later of paralysis of the lower extremities, loss of reflexes, and tenderness on pressure over nerves or muscles. Anesthesia to the umbilicus followed, but there was no Kernig's sign. A lumbar puncture was made and the findings were most remarkable. The fluid was clear, pressure moderate, 151 cells to the c.c. with deeply stained nuclei, looking like endothelial cells, few lymphocytes, and polymorphonuclears. Cultures in broth and agar were negative. The patient died after having been under observation eleven days from cardiac failure. The eye grounds had shown a beginning choked disc. No post mortem was obtained. Here there was evidently a distinct infection of an unknown character involving the meninges. Here also was suggested a condition in the nature of Landry's paralysis. A third case which from the symptoms suggested either some infection, involving the membranes at the base of the brain, or basal syphilitic meningitis, was of interest as the post-mortem revealed something entirely different than was expected. The principal symptoms were paralysis of the sixth cranial nerve, with internal strabismus and diplopia, and a staggering gait. The examination of the blood and spinal fluid showed a negative Wassermann reaction. The patient died in coma. A diagnosis was made of basilar meningitis of unknown origin. Without a post-mortem it seemed that this might well have been classed as an infectious disease of unknown character. The autopsy showed a sarcomatous basilar meningitis. Small bodies resembling tubercles were found scattered over the meninges and two small tumors in the frontal lobes were found. There was a secondary involvement of the liver and spleen. The fourth case referred to had a specific history with a positive Wassermann reaction. The symptoms suggested acute ascending paralysis or poliomyelitis, and there was a gradual but incomplete recovery. There was no response to antisyphilitic treatment. The speaker stated that he had at present under observation two cases of subacute or chronic myelitis and he questioned whether these might not be due to some toxin. Possibly in the future many of these cases of myelitis, especially when there was no evidence of syphilis, might be put down to such agents. These cases had been brought together to suggest the idea of infection or toxic poison as probably a more frequent etiological factor than had generally been supposed in various diseases of the nervous system. The question of treatment so long as they were ignorant of the infective agent was naturally only that of the symptoms, meeting each emergency as it arose. The importance of the work of our research laboratories was here further emphasized.

Dr. NEUSTAEDTER of New York said that in the matter of the analogy of the pathology of poliomyelitis and Landry's paralysis, it was true that many cases of Landry's paralysis did not present the characteristic picture of the pathology of poliomyelitis, as we accepted it to-day, namely, a degeneration of the ganglion cells accompanied by a perivascular and pericellular infiltration of mononuclear and endothelial cells. On the other hand, the Swedish investigators in the field of experimental poliomyelitis had reported cases in which there were the clinical manifestations and yet there was no perivascular or pericellular infiltration, but only a marked degeneration of the ganglion cells in the anterior horns. This was reported by Pettersson, Kling, and Josefson at the last Congress of Hygiene and Demography, and they accepted these facts as a basis upon which they might still retain Landry's paralysis as a possible form of poliomyelitis. And in the first case reported by Dr. Fisher we have a degeneration of the ganglion cells and the clinical picture was typical. As to the question of the toxin or the germ doing the work, he was inclined to differ with Dr. Fisher. The coccus of poliomyelitis as described by Flexner possessed hardly any exotoxin and that was the reason why they had no fulminant types even in cerebral affections. The children were somnolent, but there was no coma or delirium. The intellect was always intact, the child was easily aroused, and the temperature as a rule was low and of short duration. In diseases of microbic origin where the exotoxin plays the rôle we had the reverse picture. As to the endotoxin he stated that he was able to produce it from the virus and found this to possess a relatively small amount of toxic power. A suspension of a virus of which 0.1 c.c. was enough to bring down a monkey with typical symptoms of poliomyelitis would yield an endotoxin of which 10 c.c. did not kill a guinea-pig. On the other hand, the enormous perivascular and pericellular infiltration of lymphocytes showed that the microbe was doing the damage in that it multiplied enormously and destroyed the cell. One other factor in the destruction of the ganglion cells was, it seems to him, a purely mechanical one. The exudate around the blood vessels and in its interstitial spaces deprived the adjacent cell of nutrition and a consequent degeneration and ultimate autolysis ensued. He also called attention to

chorea which, while yet accepted as of rheumatic origin, might be put into the category of toxic diseases of the nervous system. Richardson had found in six cases the *Streptococcus viridans* in the blood of these patients and was able to obtain pure cultures after ten days' incubation. Other investigators also found cocci in the blood of these patients and, if he remembered correctly, chorea was experimentally produced with this coccus. So that the so-called imitation chorea might after all prove to be an infection.

Dr. FISHER, in closing the discussion, said that as to toxins without the microbes, they always produced a great effect on the nervous system. One often saw this in diphtheria where they were really dealing with the toxin rather than the bacilli. There were other elements in the pathology to be considered where one got infiltration into the walls of the blood vessels, into the cord, and into the nerve cells, themselves not necessarily toxic in origin. He was very glad that the fact that chorea might be caused by infection had been brought out.

Practical Clinical Demonstration of the Early Diagnosis of Pulmonary Tuberculosis.—Dr. ADOLPHUS S. KNOPF gave this demonstration. He emphasized the importanee of taking a eareful history in every case suspected of having tubereulosis and presented a sample blank which he used for this purpose. He cared not so much about heredity, but more about environment, more about personal than about family history. He always inquired of the patient how many children there were in the family, and he usually found that the tuberculous patient was the sixth, seventh, eighth, or ninth child. There was both a physiological and an economical reason for this. The rectal temperature should be taken more than once. The patient should always be asked about sanguinous expectoration. Hemorrhage need not be an active hemoptysis. He referred to amenorrhea as a frequent accompaniment of tuberculosis in young women. Dr. Knopf said that in making the physical examination the first thing was inspection, not only of the chest but of the whole body, even the hair, for brittle hair might mean undernourishment. One should look for obstruction in the nose or upper respiratory tract and should inspect the teeth, gums, and throat. An anemic appearance of the mucous membranes of these parts was suggestive of tuberculosis. One should look for enlarged glands, and note whether there was pectoral tension or tachycardia. By watching the movements of the scapulæ one could often tell which side was affected. The next step was palpation, by which one could verify what was seen in regard to respiratory movements. Fremitus was then observed, both subjective and objective. One could sometimes elicit fremitus by placing the palmar surface of the hand on the chest and the forehead to the dorsal surface of the hand. One should feel for the tension of the muscles over the inflamed pulmonary tissue. The next step was percussion. Dr. Knopf said he had used many varieties of percussors, but the best percussor was the finger. However, if one was obliged to percuss a great deal it might become necessary to use some instrument. One could feel elasticity with the finger, but not with an instrument. In percussing the clavicular region one should divide it into three parts: the sternal, the median, and the acrimial. After this was done one should percuss the posterior region, determining the width of the apices; this could be done by taking a pencil and marking the limits. If one was found to be narrower than the other it indicated a shrinkage of that apex and this was one of the early manifestations of tuberculosis. The speaker also reviewed the advantages of percussing the clavicular region by percussing in the fan way. One should be careful to overlook nothing and should not forget to make an examination of the axillary region. One should percuss to determine the respiratory excursion. One might find dulness not necessarily due to tuberculosis, but which might be due to a defect in the pleural mechanism. After this one might proceed with auscultation and here one should depend mainly on the ear. When he used a stethoscope it was one of the mono-variety. In listening with the ear it was advisable, especially in dispensary practice, to interpose a towel or napkin between the patient's chest and the ear, to avoid infection. He listened for a change in the inspiration which was due to internal thickening of the bronchi. This bronchial breathing might not be typical in inspiration, but later in expiration would be prolonged and roughened, and when localized in one apex it furnished definite evidence of the presence of tuberculosis. Later one got pronounced respiratory murmur localized in the apex, and the concomitant symptoms made one reasonably certain of the presence of an early tubereulosis. The warning could not be too frequently repeated that one should not wait to find bacilli in the sputum before making a diagnosis of tuberculosis, because the case must be moderately advanced if one was able to find the germs. If after this thorough examination one was still in douht as to the diagnosis the tuberculin test might be tried.

Dr. GEORGE MANNHEIMER said that there were a few standard questions which he always asked, such as "How many brothers and sisters have you?" "Are you a good eater?" "Have you been sick much during your past life?" This latter question because persons suffering with tuberculosis had a lowered resistance and easily "caught" any form of infection. As to the local examination, in making the inspection he noted the conformation of the chest and of the clavicle and sternum in relation to the ribs. He palpated a little differently from Dr. Knopf, but that did not make any difference as each one was apt to have his own way. He was also guided by certain measurements. For instance, expansion should not be below five centimeters. He had given up speaking of physical signs as the nomenclature in this respect was confusing; they did not agree as to what were called physical signs. One should not be in a hurry in pronouncing a diagnosis and should not make one on the first examination. The patient should be asked to take his rectal temperature every three hours and to bring that to the physician.

Dr. ADOLPHUS S. KNOPF said that it was a mistake to consider every flat chest a tubereulous one. One should not only watch the conformation of the chest, but should take the measurements transversely and anteroposteriorly. One should not neglect to take the weight of the patient and to find what his weight was at times in the past. One should warn the patient not to be alarmed if at any time hemoptysis occurred, but to be prepared for it and not to get excited, but to keep quiet and to send for his physician.

The Treatment of Malignancy by Physical Methods with and without Surgery.—Dr. ARTHUR F. HOLDING of New York presented this communication, which consisted of a report on the investigations made in the Physiological Laboratory of the Huntington Cancer Commission at the General Memorial Hospital and a demonstration of the methods used. He stated that the methods employed consisted of deep Roentgen therapy, fulguration (DeKeating-Hart), desiccation (Clark), and diathermia (Nagelschmidt). These were combined with surgery, radium, toxins, and vaccines, when such adjutants were indicated. The results obtained were not so much due to original methods as to the correlation of exeellent methods already deseribed but little understood and seldom used by the profession at large. These cases had been treated during the past eighteen months, so sufficient time had not yet elapsed to enable them to make a final statement as to the ultimate success. For convenience they had divided malignant disease into three classes: First, second, and third degree of malignancy. To the first class belonged the superficial lesions tending to extend out from the skin rather than into the underlying structures, and those which did not extend more than one cm. beneath the skin, and were characterized by slow growth and a tendency not to metastisize. This class of growths showed the histological formation of papillary epithelioma, basal celled epithelioma, mycosis, fungoides, and pre-epithelial keratoses. The prognosis of such cases by the methods used was 100 per cent. good. They could be cured by physical methods without surgery, pain, hemorrhage, opening up of the lymph channels, danger of infection, implantation of malignant cells, or hospital confinement, and with the best cosmetic results. They should not be treated by a cutting operation. The physical methods in the order of preference were: massive doses of Roentgen rays, desiccation, radium, destructive causties provided the more expensive equipment was not available. Cases belonging to the second degree of malignancy were the operable tumors which tended to extend rapidly into the deeper structures and were characterized by rapid growth and tendency to metastasize. Carcinomata of the breast and sarcomata were examples of this class of cases. They showed the histological formation of basal celled epitheliomata, and alveolar and medullary cancer. The methods employed were preoperative massive doses of Roentgen rays, thorough operation, and post-operative Roentgen therapy or radium

therapy. By the use of these adjuvants to the surgical treatment the percentage of recoveries was materially increased. Cases belonging to the third class were inoperable superficial and deep malignant conditions. These patients could not as a rule be cured by any method of treatment and were undesirable subjects as the ultimate prognosis was 100 per cent. bad. The symptoms, however, could usually be improved by electrical methods and radium. Cases of the second degree were sometimes treated solely by these physical methods and this gave a false sense of security and resulted in therapeutic procrastination. Of 13 cases of the first degree, nine were symptomatically cured by massive doses of *x*-ray; four by radium, and one by a combination of the two. Of ten cases of the second degree, four epithelioma of the skin and six carcinoma of the breast, all were treated by the method outlined above for this class of cases. Three were still under treatment, five were discharged symptomatically cured, and two had discontinued treatment against advice. Of 116 cases of the third degree 5.8 per cent. were symptomatically cured; 20 per cent. were improved, and 32.2 were unimproved, while 32 per cent. were dead. The problem of handling malignancy resolved itself into the proper treatment of cases of the first degree lest they develop to the second or third degree, and in increasing the palliative effects possible for external tumors of the second and third degrees so that they might be regarded as actually remedial.

Dr. George M. MacKee of New York said that the society should be congratulated on having this excellent demonstration the strongest point of which was its conservatism. While they had made no great headway in truly malignant neoplasms by either radium or Roentgen therapy alone, they had had some remarkable results from the combination of these two agents. The fact that they occasionally got a complete cure indicated that they were on the right track and that possibly with improved methods they could do still more, just as at the present time they were able to do much more than could have been done years ago. The use of these measures seemed to be warranted as a post-operative treatment in malignant disease. They had been handicapped by the difficulty in guaging the proper quantity of radium, but with the Coolidge tube this difficulty was being overcome. Dr. MacKee related his success with radium in recurrent tumors of the breast, but he did not consider these malignant but rather the old-fashioned cicatricizing cancer. With true squamous-celled epithelioma the majority of cases had failed under the *x*-ray, but Pusey of Chicago, claimed to have had 20 or 25 cases of carcinoma of the lip which he had cured; his own experience had not been so favorable. Possibly these growths were superficial, and in many of the superficial growths if one removed the scab one application of the *x*-ray effected a cure. In deep seated cancer the *x*-ray had no effect. By a combination of surgery and the *x*-ray and radium they were certainly getting good results.

Dr. Adolphus S. Knopf of New York said he had been called in consultation in a case of a malignant type of neoplasm of the pleura and would like to know if anything could be done for such a case.

Dr. Holding, in closing the discussion, said that surgery had done much for the relief of cancer and they were just trying to give it the little additional help where it had seemed to fail. As to the neoplasm of the pleura, it was probably a case of the third degree, and the most that one could do was to relieve the patient by massive doses of *x*-ray by the cross-fire method through the chest, but this was only palliative.

Dr. Gillette of New York said that two years ago he had operated on a patient in the hospital where Dr. Holding was working and removed a breast, but not long after there was a recurrence. Instead of a second operation he had turned the patient over to the *x*-ray department and there had been a marked improvement, but similar cases had not been so fortunate.

Presentation of Dermatological and Syphilitic Cases of Unusual Interest.—Dr. Mihran B. Parounagian of New York made this presentation. The first two cases were typical cases of argyria, which, from the histories, indicated that the condition was due to the application of silver nitrate in throat affections. Another patient who had received an abrasion of the thumb by striking a man in the mouth, developed all the symptoms of syphilis, a typical chancre appearing at the site of the abrasion on the thumb. Among other conditions illustrated by the patients presented were nævus vascularis, lupus vulgaris, keratosis, alopecia areata, psoriasis, and pityriasis rosae.

Dr. Arthur F. Holding of New York said that the only suggestion that he had to make was in relation to the nevus case. He had had a large number of these cases which with the carbondioxide snow treatment had obliterated these vessels. It could also be done with radium.

Dr. George M. MacKee said that these cases of argyria presented brought out an interesting point and that was that they demonstrated what he had frequently observed, namely, that argyria could be produced by the external application of silver nitrate and that it was not always necessary to administer it internally to produce this condition. The case of chancre of the thumb suggested that every lesion, like a boil, not showing pus, and that would not heal, should be treated as syphilitic. By following this plan one might abort the disease in the early stage. This was better than waiting until the *spirochete* could be demonstrated before instituting antisyphilitic treatment.

Puerperal Pyemia: Report of a Case.—Dr. Edward C. Thompson of Newburgh made this report. He stated that the patient was delivered normally on January 15, 1914. She sustained a slight median laceration of the perineum which was not sutured. On January 17 the patient began to have headache and fever, and the following day an inflammatory lesion resembling erysipelas appeared over the left side of the neck. On January 21 the physician in attendance removed from the uterus a piece of the after-birth which had a foul odor. The next day on seeing the patient in consultation the speaker found the uterus clean, but comparatively large and tender. By February 10 when Dr. Thompson was again called into consultation the erysipelas had run its course so far as local appearances were concerned but the temperature remained up, being 102°. On February 18 there appeared over the scalp a large boggy mass which was incised and pus evacuated. An autogenous vaccine of this pus was made and a pure culture of pneumococcus obtained. The patient's temperature was of a fluctuating type with marked remissions. The leucocytes were 24,000. During the following month there appeared on the scalp, neck, arms, axilla, and breast, twelve pyemic abscesses and infections of the veins in the subcutaneous tissues. These abscesses were all associated with chills, redness, or pain. The autogenous pneumococcus vaccine was injected beginning with one hundred and fifty million every three days. Local treatment consisting of hot vaginal douches with a view to facilitating the absorption of the exudate was also administered. The patient, although for a long time on the extremist list, was finally dismissed from the hospital on May 6, the local pathological condition having undergone complete resolution. It had long been known that erysipelas was occasionally associated with a puerperium, but erysipelas was usually due to streptococcus infection with a local point of entry of the invading organism. Between the streptococcus and the pneumococcus there was a long line of intermediate forms. In view of the fact that in these pyemic abscesses there was a pure culture of pneumococcus was it not fair to assume that the erysipelas was due to hematogenous infection with a pneumococcus? In respect to treatment this case was illustrative of the general rule, that, in the treatment of puerperal infections, if the infection was localized, surgery was indicated; but, if the infection was general, the vaccine treatment was indicated. Such a conservative course of treatment was indicated in a large class of cases of puerperal sepsis which came to a hospital of general mixed service when the critical condition of the patient was already a general bacteriemia.

Philadelphia County Medical Society.

A stated meeting, held October 14 at the Hall of the Academy of Natural Sciences, was devoted to a demonstration of the use of the cinematograph in medical teaching and investigation. Dr. Theodore H. Weisenburg presented pictures illustrative of "Jacksonian and Idiopathic Epilepsy." Attention was directed to the brevity and the insignificant character of the so-called tonic phase of the convulsive movements. The local origin and the circumscription of the movements in cases of focal epilepsy were well illustrated. Dr. W. M. Late Coplin demonstrated "The Circulation of the Blood in the Tail of the Tadpole." It was seen how blood-corpuscles passed through capillaries, even when adjacent to or communicating with one another, at

varying rates of speed, and how, apparently, in some regions the circulation subsided at times. Dr. ALLEN J. SMITH demonstrated for Dr. Joseph McFarland "The Spirochete (Obermeier) of Relapsing Fever in the Blood of the Mouse." The active movements of this corkscrew-like organism, the first of its kind described in the circulating blood, were clearly seen. Dr. W. M. LATE CORLIN demonstrated "The *Trypanosoma brucei*, the Etiological Agent of Nagana, African Horse Sickness, and also the Tsetse Fly and the Blood of a Mouse Inoculated with Nagana." Drs. CHARLES K. MILLS and THEODORE H. WEISENBURG presented a communication entitled "Cerebellar Localization and Cerebellar Symptomatology," illustrated by slides and films. Dr. Mills recited some of the newer developments in the study of the functions of the cerebellum and the symptomatology resulting from disease based in considerable measure upon original observations. He pointed out that the main function of the organ was motor, and in the direction of regulating or coordinating more or less extensive and complicated movements of individual parts or groups of parts. This was designated synergy. Derangements of function resulted in asynergy. The asthenia, the atony, and the astasia so often observed were merely manifestations of this fundamental disorder. Dr. Weisenburg showed in the pictures that the movements of cerebellar disease were not like those of a drunken person, but were due to the fact that the movements of the extremities followed those of the shoulder girdle and the pelvic girdle respectively. Dr. Isaac H. Jones exhibited pictures illustrative of "The Demonstration of the Vestibular Symptoms and Pointing Reactions of Baranyi in Association with Cerebellar Disease." He pointed out how rotation of a person in a revolving chair in a given direction resulted in horizontal nystagmus in the opposite direction, as did also injection of cold water into the external auditory canal on one side induce nystagmus to the opposite, while injection of warm water brought about nystagmus in the reverse direction. On the other hand, these same procedures caused deflections of the pointing finger to the opposite side of a given fixed object. These induced phenomena were employed as a basis for the study of vestibular involvement attending cerebellar disease. Dr. ALLEN J. SMITH demonstrated "The Spirochete of Syphilis." The film disclosed the method of inoculating the cornea of a rabbit with infective material, together with the resulting lesion, and finally showed the parasite in material obtained from this lesion. Also was shown the method of treating experimentally inoculated animals with arsenobenzol and the curative result. Dr. W. M. LATE CORLIN demonstrated for Dr. Joseph McFarland "Intestinal Microbes." The pictures showed the more important bacteria infesting the intestinal canal.

PHILADELPHIA PEDIATRIC SOCIETY.

AT a stated meeting, held October 13, Dr. THEODORE LE BOUTILLIER presented "A Girl with Unusual Rachitic Deformities." The patient was a colored child, ten years old, much undersized, with a vertically elongated head, a high, receding forehead, open mouth, protruding tongue, and great distortion of the long bones. Intelligence was of a low grade. It was proposed to perform a series of operations on the distorted bones in the hope of increasing the usefulness of the child.

Dr. FRANK CROZER KNOWLES presented "A Child Suffering from Molluscum Contagiosum." There were present the characteristic small, hemispherical elevations, of pearly appearances, with a central orifice, arising from a hair-follicle.

Dr. HARRY LOWENBURG presented "A Case of Infantile Syphilis Having an Unusual Family History." The patient was three months old and when it was found to present, in addition to anemia, enlarged spleen and leucocytosis, a characteristic ham-colored exanthem on the lower extremities, a Wassermann test was made and found positive. On examination the patient's mother was found also to yield a Wassermann reaction, while the father did not, as also three older children did not. No primary lesion was discovered in mother or child. Under active antisyphilitic treatment corneal ulceration developed in one eye.

Dr. SAMUEL MCC. HAMILL exhibited a child, about two months old, presenting a deficiency in the hard palate and also in the bones forming the lower jaw. From time to time attacks of cyanosis occurred. The condition was considered of developmental origin.

Dr. JOSEPH T. FLEITAS presented "A Child with Cretinism." The patient was a boy, eight years old, with impaired intelligence, soft, dry hair, rough, dry skin, and thickening of the soft tissues in various situations. *X*-ray examination disclosed enlargement of the sella turcica, leading to the belief that the hypophysis cerebri also was enlarged, and also of the thymus gland. Marked improvement, especially of the intelligence, ensued on treatment with thyroid extract.

Dr. WILLIAM N. BRADLEY exhibited "An Infant with Malformation of Hands and Feet." All four members presented either deficiency of fusion of the digits in varying degree.

Dr. JOHN H. W. RHEIN presented "A Family with Spastic Diplegia." Of five offspring of apparently healthy parents one had died of some unknown disorder. Of the remaining four children, between the ages of fifteen and five, three presented a state of spasticity involving upper as well as lower extremities with exaggerated reflexes and impaired intelligence, without eyeground changes, and beginning in all about the third year and progressing, while the fourth, now five years old, exhibited up to the present only increased knee-jerks with Babinski reflex, but with preserved intelligence and no disorder of gait. There was no evidence of syphilis, and the Wassermann reaction was negative.

Dr. J. TORRANCE RUGH exhibited "A Girl Operated on for Dislocation of the Coccyx." The patient was a girl, about fourteen years, who fell while roller-skating, injuring the lower portion of the spinal column. Thereafter she suffered greatly from pain in the situation of the coccyx, especially when arising from the sitting posture. On examination, the coccyx was found directed forward and upward toward the pelvis, and relief was afforded by a wedge-shaped resection of the bone, restoring it to its normal position.

Dr. EDWIN E. GRAHAM exhibited *x*-ray pictures from "A Case of Osteosarcoma of the Femur." The patient was a boy, twelve years old, who, following an injury, developed a swelling of the femur above the knee-joint, in association with anemia. *X*-ray examination disclosed involvement of the bone, with destruction. A diagnosis of periosteal sarcoma was made and treatment with *x*-rays and mixed cultures of streptococcus and prodigiosus was proposed.

Dr. JOHN H. JOPSON exhibited *x*-ray plates and pictures and also photographs from a case of so-called Sprengel's deformity of the scapula. There was the characteristic elevation of the shoulder and displacement of the scapula. An adventitious bone was found attached to the lower cervical spine on the one hand and the vertebral border of the scapula on the other. This was resected piecemeal and the scapula restored to its normal position. The result was satisfactory, although the patient returned to her home before corrective orthopedic exercises could be instituted.

Dr. CLARENCE ESTILL LEE reported a case of similar character and he exhibited the patient. In this instance also an adventitious bone united the spine and the scapula, and this was removed in its entirety. The specimen also was exhibited.

Dr. JAMES K. YOUNG presented "A Child with Congenital Clubfoot Cured by Operation." The little patient was born with congenital talipes equinovarus, for the relief of which, at the age of one year, the tendo Achillis and the tendons of the anterior and posterior tibial muscles were divided, and the member placed in a splint for awhile. Later, vigorous massage was practised and the affected lower extremity was brought up to a good state of nutrition and functional use, while the preexisting deformity was overcome.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

ILLINOIS STATE BOARD OF HEALTH.

January, 1914.

(*Concluded from page* 697.)

OBSTETRICS.

1. Name and give location of female organs of generation.
2. Describe and give function of ovaries.
3. What is the composition of liquor amnii, and what is its function?
4. From what structure does hydatidiform mole develop?

5. What are the anomalies of the placenta?
6. Describe congenital umbilical hernia, and outline treatment.
7. Name the objective signs of pregnancy at the fifth month.
8. Give treatment for edema of the vulva during pregnancy.
9. Name the positions and presentations in order of their occurrence.
10. Give etiology and treatment of mastitis.

GYNECOLOGY.

1. Give the etiology of metrorrhagia.
2. Give the differential diagnosis between appendicitis and ovaritis.
3. How would you diagnose extrauterine pregnancy, and what are the indications for operation?
4. What are the principal causes of incontinence of urine in women, and the indications for treatment in each case?
5. What are the causes of procidentia uteri?
6. Give the differential diagnosis of uterine fibroids.

LARYNGOLOGY AND RHINOLOGY.

1. Give the diagnosis and treatment of abscess of antrum of Highmore.
2. Give the indications for laryngotracheotomy and describe operation.

MEDICAL JURISPRUDENCE.

1. At post-mortem, how would you determine a child was born alive?
2. Give the symptoms of poisoning by mercuric chloride, and state how it can be demonstrated in a fatal case.

ANSWERS.

OBSTETRICS.

1 and 2. FEMALE ORGANS OF GENERATION: *Uterus.* The rectum lies behind and the bladder in front; it is below the abdominal cavity and above the vagina. Its position is one of slight anteflexion, with its long axis at right angles to the long axis of the vagina. The anterior surface of its body rests on the bladder, and the cervix points backward toward the coccyx.

The *Fallopian tubes* are about 4½ inches long, situated in the broad ligament, and extending from the upper corner of the fundus of the uterus outward to the pelvic wall. Their caliber is larger at the outer fimbriated end than at the inner end.

The *ovaries* are almond-shaped bodies situated below the outer end of the Fallopian tube, and between the layers of the broad ligaments.

The *vagina* is a muscular tube extending from the uterus to the external surface. The anterior and posterior surfaces are in apposition. The anterior wall is about 3½ inches long, the posterior about 4½ inches.

Function of ovaries: To develop ova, and an internal secretion.

3. LIQUOR AMNII. *Functions:* (*a*) *During pregnancy:* (1) As a protection to the fetus against pressure and shocks from without. (2) As a protection to the uterus from excessive fetal movements. (3) It distends the uterus and thus allows for the growth and movements of the fetus. (4) It receives the excretions of the fetus. (5) It surrounds the fetus with a medium of equable temperature, and serves to prevent loss of heat. (6) It prevents the formation of adhesions between the fetus and the walls of the amniotic sac. (7) It has been supposed, by some, to afford some slight nutrition to the fetus. (*b*) *During labor:* It acts as a fluid wedge, and dilates the os uteri and the cervix; it also slightly lubricates the parts.

Composition: Chiefly water, but it contains also small amounts of albumin, epithelial cells, urea, phosphates, chlorides, etc.

4. Hydatidiform mole is derived from the chorionic villi.

5. *Anomalies of placenta:* Low insertion, placenta prævia, hypertrophy, abnormally thick, abnormally small, horseshoe or crescentic shaped, lobed; degeneration, edema, infarction, calcification, or disease of the placenta.

6. *Umbilical hernia.*—"There are two varieties of this deformity. In one, a knuckle of intestine covered by skin projects from the navel. This degree of deformity is common, occurring in two per cent. of infants. It is treated by a convex button, cork, or hard rubber compress on a strip of adhesive plaster, which encircles two-thirds of the child's body. This improvised truss is renewed from time to time, and should be worn six months. In the second variety there is an exomphalic condition, due to defective development, the intestines protruding from the umbilicus covered only by amnion. An immediate plastic operation is indicated even if the mass of protruding intestines is as large as an apple. The results of this operation have been excellent."—(Hirst's *Obstetrics.*)

7. *The objective signs of pregnancy at the fifth month* are: Hearing the fetal heart sounds, ballottement, uterine souffle, and the breast signs.

8. *Treatment of edema of the vulva during pregnancy:* "If the cause can be removed, the edema disappears. The treatment of kidney insufficiency removes the dropsy of the labia associated with that condition, as it does the other dropsies of the body. If the edema is due to pressure, rest in bed, with the occasional assumption of the knee-chest posture, often gives relief. If the edema does not yield to general treatment and to hot fomentations locally, the labia may be punctured. It should be remembered, however, that even this slight operation may terminate pregnancy. The vitality of the part, moreover, is so lowered that infection and even gangrene may follow the puncture."—(Hirst's *Obstetrics.*)

9. *Presentations and position:* Vertex presentations are most frequent; of these L.O.A., R.O.P., R.O.A., and L.O.P. are the positions in order of frequency. Breech presentations are second in order of frequency; of these the L.S.A., R.S.P., and then R.S.A. and L.S.P. indicate the order of frequency. Face and shoulder presentations are next; of the face, the order is: R.M.P., L.M.A., R.M.P., and L.M.P.; of the shoulder, L.D.A. is the most common. Brow presentation is the most rare.

10. MASTITIS. *Etiology:* Infection, generally due to handling; cracked or sore nipples and overactivity of the gland with retained secretion are predisposing causes. *Treatment:* This consists in resting the part; supporting it, applying a hot boracic acid fomentation; nursing from the affected breast should be stopped at once.

Prophylactic measures consist in not touching the breasts (by doctor or nurse or patient) without thoroughly clean hands; by washing and drying the nipple hygienic conditions before labor, and the nipple and before and after nursing, and by proper attention to breasts being preserved from pressure.

GYNECOLOGY.

1. *Metrorrhagia* is a hemorrhage from the uterus at other than the menstrual periods.

Local causes: Uterine displacements, malignant disease, inflammation of uterus or appendages, fibroids, cystic degeneration of the cervix, subinvolution, ectopic gestation, abdominal tumors.

General causes: Hemophilia, scurvy, purpura, malaria, anemia, mitral disease, diseases of kidneys, or liver, acute infectious fevers.

2. In *appendicitis* the pain is of sudden onset and is localized in the right iliac fossa; there is abdominal rigidity, chiefly of the right rectus muscle, and tenderness at McBurney's point; there are usually fever, nausea, vomiting, and constipation.

In *inflammation of the right ovary* the pain is not localized, but may be bilateral, and spreads to the vagina and rectum; there is no tenderness at McBurney's point; it is usually worse just before the menstrual period, which sometimes affords relief; on vaginal examination the ovary is found to be tender.

3. "When extrauterine pregnancy exists there are: (1) The general and reflex symptoms of pregnancy; they have often come on after an uncertain period of sterility; nausea and vomiting appear aggravated. (2) Then comes a disordered menstruation, especially metrorrhagia, accompanied with gushes of blood, and with pelvic pain coincident with the above symptoms of pregnancy; pains are often very severe, with marked tenderness within the pelvis; such symptoms are highly suggestive. (3) There is the presence of a pelvic tumor characterized as a tense cyst, sensitive to the touch, actively pulsating; this tumor has a steady and progressive growth. In the first two months it has the size of a pigeon's egg; in the third month it has the size of a hen's egg; in the fourth month it has the size of two fists. (4) The os uteri is patulous; the uterus is displaced, but is slightly enlarged and empty. (5)

Symptoms No. 2 may be absent until the end of the third month, when suddenly they become severe, with spasmodic pains, followed by the general symptoms of collapse. (6) Expulsion of the decidua, in part or whole. Nos. 1 and 2 are *presumptive signs;* Nos. 3 and 4 are *probable signs;* Nos. 5 and 6 are *positive signs.*"—(*American Textbook of Obstetrics.*)

Treatment consists in removal of the product of conception, by a laparotomy, as soon as the diagnosis is made.

4. INCONTINENCE OF URINE, IN WOMEN. *Causes:* "This condition may be found in hysteria; in various injuries or diseases of the brain and spinal cord where the sphincter power of the neck of the bladder and urethra is lost, *e.g.* in certain stages of locomotor ataxia, epilepsy; in advanced tuberculosis impairing the sphincter action; in vesicovaginal fistula; dilatation of the urethra; intoxication; in various forms of stupor, *e.g.* typhoid state; it may be due to strong stimuli acting on the bladder, urethra, or neighboring parts, *e.g.* applications to neck of bladder or inner end of urethra; acute cystitis, calculus, sudden submucous hemorrhages, caruncle, fissures, inflammation in tubes, ovaries, uterus, rectum; it may be found in early pregnancy. In childhood there may be a true incontinence due to sphincter paralysis, hyperesthesia of the vesical mucosa, some localized trouble, or a nervous condition; but in the majority of cases the irritation is reflex, from such conditions as oxaluria, lithemia, worms in the bowel or vagina, polypi of rectum, eczema of vulva or perineum, etc., and is in most cases only found at night. Once the habit is formed, it may remain long after the cause is removed."—(Webster's *Diseases of Women.*) *Treatment:* Remove the cause; attend to general health; medication is of but little value; an operation may be necessary.

5. CAUSES OF DOWNWARD DISPLACEMENTS OF THE UTERUS: (1) *Pressure from above* (pelvic or abdominal tumors, ascites, tight or heavy clothing, straining at stool, muscular exertion, fecal accumulations, habitual overdistention of the bladder); (2) *weakening and relaxation of the uterine supports* (subinvolution, senile atrophy of pelvic floor, abnormally large pelvis, increased weight of uterus, puerperal traumatisms, pressure from above, traction from below); (3) *increased weight of uterus* (congestion, subinvolution, metritis, pregnancy, fluid in the endometrium, uterine tumors); (4) *traction from below* (vaginal cicatrices, falling and pelvic floor, contraction and congenital shortening of vagina, tumors of cervix or vagina.)—(From Dudley's *Gynecology.*)

6. *Symptoms of fibroids:* Hemorrhage, leucorrhea, pain, pressure symptoms (disturbances and displacements of bladder, rectum, urethra, and uterus), backache, bearing-down sensation, dysmenorrhea.

The *differential diagnosis* is as follows:

"(1) *Parauterine cellulitic deposits* show a history of a febrile condition, a sudden onset, and the fixation and sensitiveness of the uterus.

"(2) *Hematocele* shows itself in a sudden appearance, the tumor being immovable and sensitive. The tumor is at first semifluid; later it may be tympanitic.

"(3) *Ovarian tumors.*—Vaginal touch and the use of the sound will show that the tumor is not attached to the uterus. Percussion of the abdomen will give fluctuation. There is generally more deterioration of health. Solid ovarian tumors adherent to the uterus are almost impossible to differentiate.

"(4) *Pregnancy.*—There is amenorrhea. The tumor is symmetric, softer, and of more regular growth. In doubtful cases the development of fetal heart-sounds and movements will settle the diagnosis.

"(5) *Tubal diseases* can be excluded by the shape of the tumor, the great tenderness, and lessened mobility of the uterus.

"(6) The area of displacement of a *floating kidney* will appear above the pelvic brim, while that of a fibroid is below the inlet."—(Wells' *Compend of Gynecology.*)

LARYNGOLOGY AND RHINOLOGY.

1. ABSCESS OF ANTRUM OF HIGHMORE. *Symptoms:* "There is pain, tenderness on pressing over the canine fossa or on tapping the teeth of the upper jaw, and sometimes swelling of the cheek. The complaint of a bad odor or taste, the reappearance of pus in the middle meatus after mopping it away and directing the patient to bend his head well forward, and opacity on transillumination of the suspected cavity are signs which strongly suggest an affection of the maxillary sinus. The withdrawal of pus by a puncture through the thin outer wall of the inferior meatus of the n with a fine trocar and canula will establish the diagn sis. The *treatment* consists in opening and drainin the antrum. If the infection is due to a carious tooth this should be extracted, the socket opened up and drainage established through it. If the teeth are sound the antrum is opened through the canine fossa and its walls curetted, after which the cavity is packed with iodoform worsted. To avoid the risk of reinfecting the cavity from the mouth, an opening may be made into the nose, by removing the anterior portion of the nasal wall of the antrum and part of the inferior turbinated bone, after which the incision in the buccal mucous membrane is closed with sutures."—(Thomson and Miles' *Surgery.*)

2. "Laryngotomy is rarely undertaken except for the relief of dyspnea arising from some sudden obstruction to the respiration, and is thus to be looked on as an operation of urgency. It is required in cases where the entrance to the larynx is obstructed by a foreign body, for spasm of the glottis, or for accumulations of blood in the neighborhood of the larynx during an operation. It is readily performed by making a vertical incision over the situation of the cricothyroid membrane, which is then divided transversely along the upper border of the cricoid cartilage, the sternohyoid muscles being, if necessary, drawn aside, and a tube inserted. Possibly the small cricothyroid artery arising from the superior thyroid may require a ligature. In cases of great urgency, a simple transverse incision may be made with a penknife, and the larynx opened, the margins of the wound being held aside by a hairpin, or by the handle of a scalpel turned edgeways, while a toothpick will serve temporarily as a cannula. Whenever there is time to operate deliberately, a high tracheotomy is the better practice, since a tube inserted through the cricothyroid space gives rise to considerable irritation, and the voice may be subsequently impaired by the contraction of the cicatrix. A special laryngotomy tube is required, the lumen of which is not circular, but oval and flattened from above downward."—(Rose and Carless' *Surgery.*)

MEDICAL JURISPRUDENCE.

1. If respiration has taken place, its lungs will float on being put into water. Further, the lungs before respiration are situated at the back of the thorax and do not fill the cavity; whereas, after respiration they fill the whole cavity.

Application of hydrostatic test.—Having opened chest, note *position* of lungs (*before* respiration they occupy a small space at upper and posterior parts of thorax); their *volume* (of course increased after breathing); their *shape* (before respiration, borders sharp or pointed; after it, rounded); their *color* (before breathing, brownish-red; after it, pale red or pink); their appearance as regards disease and putrefaction; and whether they *crepitate* on pressure (as they will *after* respiration).

"Take out lungs, with heart attached, and place them in pure water having temperature of surrounding air. Note whether they float (high or low), or sink (slowly or rapidly). Separate them from the heart; weigh them accurately, and then place them in water again, and note sinking or floating as before. Subject each lung to pressure with the hand, and note sinking or floating again. Cut each lung in pieces and test floating again. Take out each piece, wrap it in a cloth, and compress with fingers as hard as possible, and test floating, etc., as before. The crucial test of *perfect respiration* is each piece floating after the most vigorous compression."—(King's *Manual of Obstetrics.*)

2. *Symptoms of acute poisoning by mercuric chloride:* The nauseous metallic taste is experienced during the act of swallowing. Within a few moments this is followed by an intense, burning pain in the mouth, throat, and stomach. The mouth and tongue are whitened and shriveled. There are vomitings of a white material, containing shreds of mucous membrane, and tinged with blood, and bloody stools. Salivation occurs if life be sufficiently prolonged."—(Witthaus.)

Mercury may be detected in the urine or vomited material by the Reinisch test. To the suspected fluid add a little pure HCl; suspend in the fluid a small strip of bright copper foil, and boil. If a deposit forms on the copper, remove the copper, wash it with pure water, dry on filter paper, but be careful not to rub off the deposit. Put the copper into a clean, dry glass tube, open at both ends, and apply heat where the copper is. If mercury is present it will be deposited in the cold part of the tube, forming a mirror.

ALBUMIN IN SPUTUM AND ITS RELATION TO PULMONARY DISEASE.*

BY GEO. R CALLENDER,

FIRST LIEUTENANT, MEDICAL CORPS, U. S. A.

U. S. ARMY GENERAL HOSPITAL, FORT BAYARD, NEW MEXICO.

IN the past few years articles based on the chemical examination of the sputum have been numerous, but few of them have dealt with the work of foreign investigators, and those few only incompletely. For this reason the writer has attempted to cover all the more important articles and to give in the appended list either all the references or the places where the valuable material from all may be found.

The first mention of the chemical examination of the sputum in pulmonary disease is by Coventou, as quoted by Kauffmann. Coventou in 1843 treated the sputum with chlorine water and found that in ten days there appeared a bluish opalescence in the sputa of the phthisical, while that from patients afflicted with acute and chronic bronchitis became a reddish or brownish color.

Von Biermer in 1855 analyzed the sputa from various respiratory diseases and found as constituents decomposed albumin, paralbumin, mucin, salts, etc. His findings tabulated are as follows:

1. Chronic bronchitis = Mucin, many salts, no albumin.
2. Acute pneumonia = Mucin and albumin;
3. Active pneumonia = Mucin and much albumin;
4. Edema of lungs = Little mucin, much albumin.

Renk (1875) found no albumin in chronic bronchitis but did find it in acute bronchitis, phthisis, and pneumonia. In this same year Kössel reported the finding of peptone in purulent sputum.

From this time until 1908 the bacteriological examination, claimed the interest of investigators to the exclusion of the chemical methods. After many observers had found that the tubercle bacillus was not constantly present in the sputum of the phthisical, investigators began to try other methods to determine the presence or absence of the disease.

About 1903 Müller and Wanner, closely followed by Roger, took up the albumin reaction in sputum. Müller and Wanner found either no albumin or a negligible quantity in chronic bronchitis and asthma, but found it abundant in pulmonary edema and congestive catarrh secondary to heart and kidney disease, and constant in phthisis. A distinct precipitate they consider is to be referred to phthisis.

Roger, who at the present time has collected data from over 1600 cases, concludes that albumin is not present in either acute or chronic bronchitis, and that its continued absence usually excludes tuberculosis. He further states that this reaction may serve to differentiate early cases; the disappearance indicates healing and cures, while a reappearance indicates a recrudesence. Both types of pneumonia, lobar and lobular, as well as the congestive conditions, were found to give rise to the presence of albumin in the sputum.

V. Raymond considers that the albumin in the sputum is a sign of inflammation of the parenchyma of the lung, which is often but not always of tuberculous nature. He considers the reaction, while valuable when taken in connection with other signs, is not at all diagnostic in itself.

F. Schmey believes the reaction important in the early diagnosis and says that it is present in all but the uncomplicated fibrous conditions. More than 2 per cent. he considers diagnostic of phthisis, if pneumonia and congestive conditions are excluded.

Ljubarsky found an average of 2.7 per cent. in 25 known tuberculous cases, with no negatives. The more widespread and active the disease the more albumin was found. In acute bronchitis 11.1 per cent. and in chronic bronchitis 39.1 per cent. of cases contained albumin in the sputum. In the last named disease the author suggested that the cases might have been tuberculous though the albumin reaction was the only indication. He agreed with Roger as to the value of a negative reaction.

Busnikowa finds that in diseases of the parenchyma the reaction is positive, but negative in disease of the air passages. This author reports a case of pleuritis sicca, negative for bacilli but positive for albumin. Later there developed an apical lesion with positive bacillary findings.

Levy-Valensi found that albumin was generally present in tuberculous sputum, but not all positive reactions indicated tuberculous disease. He considers that cases of bronchitis, negative for bacilli but positive for albumin, are tuberculous.

Peskow in a series of 67 cases emphasizes the importance of the reaction in differentiating between simple bronchitis and tuberculosis. He maintains that a negative reaction excludes disease of the lung parenchyma including tuberculosis.

Luczinin in 15 cases of diseases of the lung, heart, gastrointestinal tract and nervous system found albumin in all. Quantitatively the albumin reached 3 per cent. (Esbach) in most cases of tuberculosis while in other diseases it was decidely less. In the initial stage of phthisis he considers that an albumin content of over 1 per cent. justifies a positive diagnosis. In severe acute and chronic bronchitis, pneumonia and emphysema the albumin content did not exceed 0.5-0.6 per cent.

Gelderblom reports 75 cases in which albumin was always found coincident with fresh tuberculous processes in the lung and believes that the rise and fall of the albumin content indicates the course of the disease and the prognosis.

*Published with the permission of the Surgeon General, United States Army.

Foullerton in 100 cases used four tests for albumin and only considered those positive that reached to all four. He concluded that in most cases of tuberculosis there is considerable albumin, that it is also present in bronchitis and pneumonia, and that the reaction is unreliable.

Works after examinations in 100 cases concludes that a negative reaction excludes tuberculosis.

B. G. Williams in 37 cases of tuberculosis found albumin constantly present.

Scott in 85 cases of tuberculosis positive for bacilli found in 32 early cases, albumin positive in 15, doubtful in 11, negative in 6; in 53 advanced cases, albumin positive in 39, doubtful in 12, negative in 2; in 85 in all, albumin positive in 54, doubtful in 23, negative in 8. In this series we see nearly 10 per cent. negative and nearly 20 per cent. of the early cases failed to show the reaction. If we exclude doubtful reactions which are certainly of little value in differential diagnosis, there are over 30 per cent. negative.

Hempel-Jorgenson obtained results differing rather markedly from those of the majority of investigators. He found that the albumin content varied with the portion of the sputum taken for the reaction, the thicker purulent portions containing a larger amount than the thinner and more mucoid. Other authors including the writer have found that while this is usually so, often we find sputa with little or no pus but abundant albumin and others with much pus and very little or no albumin. The latter condition indicates that the pus cells had not become autolyzed and therefore were filtered out.

The amount of shaking necessary to obtain the maximum of albumin from a given sputum he found to depend on the consistency, and other authors, including the writer, concur in this finding.

Hempel-Jorgenson reported 2 cases, one with abundant tubercle bacilli in the sputum and the other an advanced case as proved by subsequent autopsy, in both of which the albumin reaction showed the presence of only very small traces. In 16 other cases, undoubtedly tuberculous, the amount varied from that indeterminable quantitatively to 12 per cent. In 10 cases of bronchitis and asthma, this author found from traces to 1.8 per cent. In one case where the heart condition was abnormal the amount was 3 per cent. In a case of gangrene of the lung 3.5 per cent. was present. Hempel-Jorgenson concludes that the reaction is of no value in the diagnosis of the early stages of pulmonary tuberculosis.

Goodman found 15 negatives in 38 cases of known pulmonary tuberculosis.

Biernachi holds that over 2 per cent. of albumin, if other diseases, as congestion and pneumonia, are ruled out, indicates tuberculosis.

Pindborg in 265 cases found only 37 per cent. contained over 2 per cent. of albumin. In this series 61 cases were in the first stage and of these only 2 or 3.5 per cent. contained over 2 per cent. of albumin.

Corning believes the reaction to be of undoubted value in some of the cases difficult to diagnose.

Lewis found albumin in all sputa examined but failed to classify the reaction.

Gantz and Hertz found 57 positives in 60 cases of phthisis. The negatives were two fibrous cases and one with widespread and active tuberculous disease as proved by subsequent autopsy.

Melikjanz found varying amounts of albumin in the sputa of the phthisical, but in general the amount corresponded to the activity. In the nontuberculous the amounts were always less. His results in this respect do not agree with many other investigators, though they did not use the same method in determining the quantity of albumin (Brandenberg-Stolnikoff). He found only minimal quantities in conditions of passive congestion while others have found 2 per cent. and over. In differential diagnosis this author states that whereas there is albumin present in other diseases and therefore the qualitative determination is of no value, the quantitative estimation will exclude emphysema, acute and chronic bronchitis, bronchial asthma, and conditions secondary to heart and kidney disease, while the diseases, such as abscess of the lung, which in his experience give rise to the larger amounts, are easily excluded clinically. Let us glance at a few of his results. In seven cases of tuberculosis involving from apices with 0.36 per cent. albumin to two lobes with 0.86 per cent. we see rather small amounts, while in cases of nephritis with congestive conditions in the lung his percentages were 0.36 per cent., one case; 0.53 per cent., two cases. To be sure the diagnosis was probably easy clinically but wherein did the quantitative estimation of albumin aid? He found little albumin in pneumonia crouposa while others (Wanner 3 per cent.) have found the largest quantities in some stage of this disease.

As to the value of the albumin determination as compared with the bacteriological examination the following table was quoted from the clinic of Dr. Rollier in Leysin, by Melikjanz:

Stage of Disease	No.	Alb. Pos.	Alb. Neg.	Tbc. Pos.	Tbc. Neg.
I	28	26	2	3	25
II	50	50	0	44	6
III	40	40	0	40	0
Totals	118	116	2	87	31

The value of this table is seriously impaired by the fact that the author makes no note as to the activity of the cases recorded. If it is presumed that all cases were active the search for tubercle bacilli was surely not fruitful in the cases in the first stage, only a little over 10 per cent. being found positive.

Hempel-Jorgenson found that the albumin content decreases with an improvement and increases with an advance of the disease, thus in a way indicating the prognosis.

Dr. Blümel in a review of the work on this subject divides the investigators into three groups. The extreme advocates of the method headed by Roger and the French school, the intermediates of which Kauffmann is the most prominent exponent, and the dissentors in which class belong Pindborg, Hempel-Jorgenson, and others. Blümel's own observations in over 100 cases emphasize the importance of using a 24-hour amount of sputum and that the sputum must come from the parenchyma of the lung. Secretions of the nose and nasopharynx in atrophic rhinitis, ozena, and inflammations of the accessory sinuses mixed with the sputum give rise to a positive reaction. This author concludes that a percentage of albumin of over 2 is suggestive of turberculosis if such diseases of the parenchyma as pneumonia and congestive conditions are excluded. The reaction fails in fibrous phthisis as often as in early cases of tuberculosis. Blümel has very appropriately placed

Kauffmann in the intermediate group, as this author evidently approached the question with an open mind in an endeavor to sift out the causes for the widely dissenting views or to support one view or the other. For this reason Kauffmann's views will be considered here at length.

There were 108 cases in Kauffmann's series, over half of which were detailed. The negative cases were from the group of chronic bronchitides while the positive were tuberculosis, pneumonia, and bronchiectasis. There was not a single case of established tuberculosis of the lungs in which albumin was not demonstrated.

From his results with tuberculosis he concludes that while the albumin reaction is interesting it is not of value until the second and third stages of the disease when the diagnosis is already established by other methods; though he considers the reaction confirmatory in a similar though not as emphatic a manner as the finding of bacilli.

An interesting and valuable observation made on several cases was that the reaction may be stimulated by the use of tuberculin, in one miligram doses. Only two cases had been previously reported, one by Roger and the other by Gaeerard. The latter formulated a schema in relation to the two reactions.

I—Cutaneous reaction Neg., Alb. Pos. = Lung disease, non-tuberculous.

II—Cutaneous reaction Pos., Alb. Neg. = Latent tuberculosis.

III—Cutaneous reaction Pos., Alb. Pos. = Active pulmonary tuberculosis.

From this Kauffmann concludes: "The reaction of the organism to the subcutaneous injection of 'old tuberculin' demonstrates that there is a tuberculous focus somewhere in the body, but as to where it lies and whether it is progressive or not we have no clue. This reaction with the demonstration of albumin proves that a reacting focus does not lie in a lymph gland or any other place but in the lung."

Kauffmann found that early cases may have much, late cases little albumin, and vice versa, and Roger had similar experiences.

Smolizanski alone seems to think that the amount of albumin and the extent of the process correspond. Kauffmann says that even if Smolizanski is right, which he doubts, the cost and complexity of the apparatus as well as the time consumed make the quantitative determination impracticable.

As to prognosis he thinks that a continued decrease in albumin indicates a favorable outcome at least for that attack or exacerbation. In one of his cases and in seven similar ones reported by Ferrera, the albumin became less and less and finally disappeared during a favorable course of the disease and reappeared when exacerbations occurred. He considers that a quite accurate prognosis may be made by determining the relation between the albumin and globulin contents as both Smolizanski and Roger have demonstrated. They contend that the preponderance of serum albumin goes with a rapid course of the disease while a preponderance of globulin accompanies the favorable cases and those showing tendencies to heal. He reports a case of phthisis formerly diagnosed bacteriologically which on admission showed only a bronchitis such as he says is frequently found about old healed lesions, in whose sputum globulin only was found. Dieudonné reported four similar cases.

In bronchiectasis albumin was found. In one case of this disease with positive albumin an artificial pneumothorax was produced, thus compressing and obliterating the cavities where the autolysis of tissue and exudate was taking place. Following this operation the albumin disappeared from the sputum only to reappear when the nitrogen introduced became absorbed.

In pneumonia the albumin content of the sputum was found to be greatest at the crisis when the most active autolysis of tissue is taking place in the exudate and gradually disappears. Kauffmann reports two and Roger fourteen cases of this character. On the other hand, if a second process, as a new pneumonia or an empyema occurs, the albumin will continue or reappear. Waurmann reports one case of a new pneumonic focus and another of empyema in which this occurred.

In tuberculous pleurisy with effusion albumin is found in the sputum. Kauffmann reports three cases of this character. His conclusions are: (1) The test for albumin is an easy bedside manipulation. (2) Albumin is found in the sputum in tuberculosis, pneumonia, congestive catarrh secondary to heart and kidney lesions, fetid bronchitis and bronchiectasis, not in chronic bronchitis. (3) The albumin with the tuberculin reaction will substantiate the diagnosis of an active tuberculous focus and whether that focus is in the lung. (4) In cases of healed tuberculosis the albumin reaction disappears. (5) In pneumonia the albumin disappears gradually after the crisis and its continued presence or reappearance indicates a new pneumonia, an empyema, or a tuberculosis of the lung.

Sputum as considered in diseases of the respiratory tract is material raised to a large extent by coughing and expectorated. It contains the products of the disease in the air passages and parenchyma of the respiratory tract as well as the normal secretions increased in amount to some degree by the inflammatory processes. With these secretions saliva is mixed. Saliva contains in addition to enzymes and various salts, varying amounts of globulin, though in quantities too small to give more than an opalescence in the fluid sputum with reagents causing its precipitation. Mucin in demonstrable quantities by acetic acid precipitation is a constant finding in saliva and in the secretions of all mucous membranes. In conditions of passive congestion there is added a transudate. Transudates as in the pleural and peritoneal cavities contain from 0.5 per cent. to 2 per cent. of albumin. In inflammatory processes there is added an exudate. Exudates contain from 2 per cent. to 6 per cent. or more of albumin. Now the purulent material of an exudate is composed of leucocytes, fibrin, and cell detritus, all of which contain albumin, but in order for it to be detected in the filtrate from the original material the cells containing it must be broken up by autolysis. This autolysis of the cells and lysis of the fibrin is accomplished by the ferments of the leucocytes. Thus leucocytes, cells, and fibrin may be filtered out and consequently give no reaction, while if the material has remained some time in the bronchi or their dilatations, cavities, or alveoli, as in pneumonia, or in the sputum cup, lysis of these albumin-containing elements takes place and the soluble albumin is then detected.

Wanner considers the origin of the albumin to be the glands of the mucosa, the blood vessels of the bronchi and alveoli, and ulcerations. Any albumin content over an opalescence is to be attributed to inflammation and a content of over 9 per cent. to a vascular lesion.

Schmoll says that the larger part of the caseous material formed in tuberculosis is coagulated albumin.

As Melikjanz says, no disease of the varieties considered in this work produces such widespread destruction of tissue as tuberculosis; even the relatively resistant elastic tissue yielding readily to its attack. Also in tuberculosis we have a process noted for the formation of new cells in excess of those normally present. Thus Melikjanz draws the conclusion that from this maximum of destructive ability combined with the increased amount of destroyable material arises the albumin content in the sputa of the tuberculous.

Similarly in any disease of the destructive variety in the lung, material is thrown off as the result of its destruction. If it has not become autolyzed no albumin content will be found after a filtration except from exudation of soluble albumin; while if autolysis has taken place the reaction will be positive. The inflammatory exudate about new tubercles is largely serous in character, and contains little or no fibrin, is immediately filterable, and gives a positive reaction for albumin.

Technique.—There are many reactions for albumin. The qualitative are simple and practical while the quantitative are difficult and complicated. The most simple of the latter (Esbach's) is notoriously inaccurate and the more exact as Claudius' or the colorimetric and Brandberg-Stolnikoff's (involving the dilution of the material until a ring is formed by Heller's nitric acid test in three minutes), as well as the most accurate or weighing method are far too complicated.

If this reaction is of any value the method must be practical, applicable by those without special equipment and abundant time at their disposal. Again, complications in technique foster inaccuracy and are therefore to be avoided. In a review of the results of various authors it does not appear that the quantitative determination has added to the value of the results of the simple qualitative test, though it must be admitted that considering an opalescence as negative borders on the quantitative without annexing its undesirable complexity.

Various precipitants are applicable as heat and acetic acid, picric acid, nitric acid, and 10 per cent. potassium ferrocyanide.

Nitric acid is inaccurate for this work as the element of time enters too strongly and the reading is difficult. Ten per cent. potassium ferrocyanide in acid solution is the most simple and uniform in its results, as well as the most rapid.

The following is the technique used by the writer after trials of all other recorded methods, and it is recommended for those who desire to continue work with this procedure.

1. Twenty-four-hour amounts of sputum are collected and examined fresh. This is necessary as any portion may contain all mucus or all material from the disease process. It is even reasonable to suppose that differences in day and night specimens as recorded by Lieut. Priest, formerly of the staff of this hospital, may be explained in this way. Many cases though constantly expectorating may only at times raise material representative of the pulmonary process.

2. The material is placed in a glass-stoppered flask, an equal quantity of 3 per cent. acetic acid added, and the mass rendered homogeneous by shaking. No definite time can be allowed because of the varying consistency of the sputum.

3. Allow to stand for 5 minutes and filter. An interval of 5 minutes before filtering allows the mucin to collect in larger masses and filtration is more rapid and satisfactory. Add one drop of glacial acetic acid to the filtrate to be sure of complete precipitation of mucin and repeat filtration if necessary.

4. Take a convenient quantity, as 4 c.c., and add an equal volume of supersaturated magnesium sulphate solution, about 80 per cent. (This solution may be made at 60° C. and kept in the 37.5° C. incubator.) This precipitates globulin.

5. To another similar portion add 5 drops of 10 per cent. potassium ferrocyanide to precipitate albumin. If much globulin is found to be present by the first determination it will be necessary to filter it out before proceeding with the test as the ferrocyanide precipitates both. Except in work involving an estimation of the prognosis and where globulin is more than an opalescence this is rarely necessary.

The following symbols are used in recording results in the tables. ++ denotes a distinct heavy precipitate appearing immediately on addition of the reagent; + a precipitate of less amount and forming more slowly. In the case of globulin precipitates form slowly and tend to remain in suspension. It was found that the heavy clouds formed in the reaction will form precipitates if given a little time. The negatives then are reactions showing no change in the clarity of the material or an opalescence or cloudiness that does not settle as a precipitate and such as may be obtained from the sputum of persons with no respiratory disease; *Tbc* is used to indicate tubercle bacilli; *Muc. Pur.* to indicate mucopurulent.

One hundred and eight cases are tabulated below. Following the tables are cases in addition illustrative of special conditions.

Quantitatively we have been unable to find more than 2.5 per cent. of albumin in any of the sputa examined and many of the third stage cases were active in the extreme, clinically, and a few have proved the amount of activity on the autopsy table.

The classification of cases is according to the modified Turban classification.

GENERAL TABLE

Class	Activity	No.	Tbc.		Albumin			Globulin			Sputum	
			Pos.	Neg.	++	+	0	++	+	0	Muc. Pur.	Mucoid
Incip	Slight	5	4	1	3	2	0	1	2	2	3	2

TABLE BY CONDITION OF SPUTUM

Condition	No.	Albumin			Per Cent Pos.	Globulin		
		++	+	0		++	+	0
Mucoid	11	5	3	3	72.7	0	8	3
Mucopurulent	97	71	14	12	87.6	43	36	18

A glance at the table recording results in regard to the character of the sputum shows that the albumin content is relatively independent of this factor. Further work with different portions of the same sputum shows that frequently the nonpurulent portions contain as much and sometimes more albumin than the purulent.

In our work we will first consider the table made from known tuberculous cases, primarily diagnosed by the finding of tubercle bacilli. Of these 103 were active yet, 15 of the 103 were negative by repeated examinations for albumin, or 14.5 per cent.

Incipient active cases all showed a positive reaction. Of the moderately advanced cases 40 or 80 per cent. were positive and of the far advanced 90.3 per cent. contained albumin. One of the negative cases in the far advanced series was clinically *in extremis*, but repeated trials failed to show the reaction. The incipient cases show a result rather favorable to the diagnostic significance of the reaction but too few cases were available as most of the cases of this class in this institution are inactive. On the other hand there is a large percentage negative in the moderately and far advanced cases. It must be considered that the activity in at least some of these may have been diagnosed by moisture due to other causes than tuberculous activity, though every one of the doubtful cases showed bacilli in the sputum if not at the time of the examination, at least at the last examination, within one month previous.

Of fibrous cases, 10 cases were examined in a separate group. Of these 2, or 20 per cent., were positive for both albumin and globulin; the rest being negative for both. Both of the positive cases showed periodically tubercle bacilli in the sputum and it is therefore possible that there was some activity present. In this class of cases there is usually the question whether signs present are due to activity of the tuberculous process or moisture surrounding healed foci and the albumin reaction if positive, seems to indicate activity.

W., a cardiac case, showed during partial compensation a plus (+) reaction. Two months later, when compensation was complete, though raising some sputum, the reaction was negative.

R. and P. both showed considerable trouble and there was a question whether the signs present were those of tuberculous activity or bronchitis. Double plus (++) reactions in both cases indicated activity and their subsequent history has substantiated the findings.

Y. and B. G. W., cases of bronchial asthma with negative bacillary findings, were repeatedly negative.

N., a case of pulmonary syphilis, showed abundant precipitates of both albumin and globulin. In this connection observations by Waurrmann and Melikjanz are interesting. The former reports two cases of pleural disease in which the albumin reaction in the sputum was negative but the pleural fluid gave a positive Wassermann reaction.

This finding, as Kauffmann says, does not prove that the process was syphilitic but only that the patient was. Melikjanz reports a case of pulmonary syphilis in which no evidence of tuberculosis could be found, whose sputum contained 1.35 per cent. of albumin. The case cleared up and the sputum became negative for albumin under anti-luetic treatment.

R., a case of fibrinous bronchitis, showed at all times a small amount of albumin not estimable quantitatively.

B., a case of subacute bronchitis, and X., a case of bronchiectasis, similarly showed small amounts of albumin.

Two cases of subacute rhinitis and nasopharyngitis showed constantly in the purulent sputum a small amount of serum albumin thus coinciding with the report of Dr. Blümel. The amounts were sufficient to cause a confusing reaction and the secretion of the nasopharynx and nares must be looked on as a source of error.

Three cases in which artificial pneumothorax had been produced showed on first examination a trace of globulin and a heavy albumin precipitate. Two months later all three cases clinically showed a marked improvement and in all three the globulin had increased to a double plus (++) reaction while the albumin was present only in traces.

From the experience of the writer in all cases in which the globulin was tested for it was found that one examination did not in any way indicate the prognosis. Repeated examinations at sufficient intervals were necessary. Considerable globulin may be present and frequently is in sputa containing abundant albumin and in cases showing no tendency to heal, but in these the albumin preponderates and continues to do so.

Miliary tuberculosis is apparently an exception to the rule that albumin is found in all destructive processes of the lung. This is without doubt, due to the fact that there is not sufficient destruction of the parenchyma before death and little exudation into the air passages, but most of the material expectorated represents the increased secretion of the mucosa. Darrasse and Roger each report a case bearing out this conclusion.

Deductions from the work of the writer: 1. Albumin is not present in the sputum from all cases of *active* pulmonary tuberculosis. This seems indisputable. Doubtful and negative cases are not reported in this paper without several examinations at sufficient intervals to justify the record of negative albumin. A case has been considered active if clinical signs indicated it and if the bacilli were found within one month of the examination for albumin. As a corrolary to this first conclusion it may be said that the percentage of negatives in the active cases is sufficient to seriously affect the value of the reaction from a diagnostic standpoint.

2. An increase in globulin accompanied by a decrease in albumin is a favorable prognostic sign.

3. Albumin is present in the sputum from cases of pulmonary syphilis and is therefore not a means of differential diagnosis between that disease and phthisis.

4. As a general rule, though there are exceptions, the albumin content corresponds to the amount of activity.

5. Fibrous cases with moisture but no active tuberculosis in the lungs do not show appreciable amounts of albumin in the sputum. Thus the determination of albumin may be of aid in the dif-

ferential diagnosis between moisture due to tuberculous activity and that due to other causes as in the fibrous tissue of an old healed lesion or surrounding such and due to congestion.

It seems to me, from the diverse results we must conclude that for diagnosis, direct or differential, albumin in the sputum either quantitatively or qualitatively determined, while possibly acting to substantiate other methods, is of very little value alone. As in many other reactions a positive result is of more value than a negative.

Many other diseases give a positive reaction; some being easily differentiated while others are not. The disease most frequently offering difficulty in differential diagnosis is bronchitis, including bronchiectasis. If the reaction is strongly positive bronchitis is probably ruled out. Bronchiectasis, if of slight degree, may likewise show only a slight reaction, but if severe and with abundant cavities or large dilatations allowing stagnation and autolysis of exudate, the albumin content may be very large.

Many authors emphasize the importance of determining the source of the sputum. This is difficult and many times impossible. The sputum in the actively tuberculous may be almost entirely from an inflamed mucosa and therefore contain little or no albumin. This secretion alone or diluting that from the parenchyma certainly will give an erroneous reaction.

There may be such differences in the activity and amount of exudation of pulmonary tuberculosis that the quantitative estimation has scarcely the importance attributed to it by some observers and practically the technique is far too cumbersome to be of value.

In apparent exacerbations of the disease the reaction may serve to differentiate true activity from bronchitis and in the course of the disease a progressive diminution to total absence may indicate healing; a reappearance or increase, an exacerbation.

The writer can scarcely credit the reaction with an importance even approaching that of the examination for bacilli.

In conclusion the writer wishes to thank Colonel Bushnell, Medical Corps, United States Army, and the clinical members of the staff of this hospital for their assistance in obtaining literature and material.

PROBLEMS OF LIFE.

A REVIEW OF THE SCOPE OF OUR PRESENT KNOWLEDGE ON THE SUBJECT.

By HENRY M. FRIEDMAN, M.D., LL.M.,

NEW YORK.

ACTING ASSISTANT SURGEON, UNITED STATES PUBLIC HEALTH SERVICE.

"This fine old world of ours is but a child
Yet in the gocart: Patience! Give it time
To learn its limbs; there is a hand that guides."
—*Tennyson.*

ONE must not be entirely what is commonly called a "fatalist" to perceive that there can be nothing in all Creation, known at present, or that is to be discovered in the future, but must have a definite and distinct place in the *morale*, in the economy, or even in the materiality of life. It matters little how theoretical a discovery now appears, it must only be a fact, and it is certain to have practical application, perhaps preordained by the Creator to meet the urgencies of human progress, somewhere, sometime, or some place in this vast universe. Indeed, we can go a step further. We can say that the theories of yesterday are no longer theories. They are the facts of today, accepted by everyone as matters of fact as if they had never been in the stage of theory. Theories advanced and the researches conducted in life, no matter of what phase, whether of the theories of its origin, or of the more practical factors of its prolongation, must result to the advantage of that life; and the life given us to live will the better be able to fulfill its mission on this earth. Those who view with misgivings the expenditure of vast amounts of energy and of large sums of money in the study of wholly theoretical matters, *i.e.* in scientific research, in the face, apparently, of many more urgent necessities, must soon have brought home to them the knowledge that these expenditures have been the means of discovering truths in Nature of positive—yes, even material, value to life, and in the conservation of it. But when we ask the simple question—of life, "What is it?"—or when we presume to inquire into the nature of the many circumstances and phe-

nomena surrounding it, we find that they are still veiled in a great deal of mystery. To be sure, the lore is crowded with many interesting theories; and while these have thus far been the means of solving but comparatively few of its problems, they have cleared trackless fields of investigation, that already bear fruit, with promises of boundless futures.

The Origin of Life.—When we set out to inquire into the phases of life we find ourselves at once baffled by our lack of insight into the very nature of life. It may be that Providence has thus far wisely kept this knowledge from mortal man. All that we do know about any aspect of life is, at best, only parallel or adjective to it. About the nature of the forces controlling it, and even about many of the processes we are as much in the dark as ever. It is the opinion of some students of this subject that life is chemical in nature. The successful fertilization, by chemical means, of the egg of the sea urchin has convinced many of the truth of this postulate. The fact that the lower fungi have taken life in sterile chemical solutions is pointed to as another proof. Even admitting the truth of these observations, no proof is advanced that there was not life in the subject of observation, and that the chemicals were not merely the media in which the life developed. Indeed, the phenomena of the fungi are explained by the opponents of the chemical origin of life on the ground that there was not complete sterilization of the chemical solutions, and that on the withdrawal of the sterilizing agency, the organisms not so destroyed—if, indeed, human beings possess any means for the total destruction of this incomprehensible fact of life—again begin their life activity. This is consistent with bacteriological knowledge. It is known that the reproductive elements, the spores, of certain bacteria have a tendency to resist the most powerful destructive agents, and assume life again after the removal of these agencies. Theories can be multiplied indefinitely, and with this subject the more theories the more mysteries. The origin of life is a question that has always haunted man even from "time when the memory of man runneth not to the contrary." It almost seems that since at all times all peoples, no matter how crude they were, or how high a degree of civilization they have attained, have answered this question from the spiritual standpoint, that it is on these grounds that this question must finally be answered.

Theologians and scientists must never be at loggerheads. They are working in different fields. The scientist wants to know only the methods or processes by which Nature, and more specifically—life, works. He seeks knowledge that Nature holds out for him to conquer. The theologian is interested in the spiritual phases of life; those phases which seek especially to promulgate the religious and social duties of mankind without the proper understanding of which man does not seem to be able to enjoy the material gifts of this world. In the strictest interpretation of the term "origin," it can be seen that it is a matter with which theology is most concerned. It is concerned in tracing and crediting the gifts of Nature—matter, life, this vast whole—the universe, to its origin with the Donor. That eminent naturalist, Professor Tyndall, carried away, no doubt, by his enthusiasm, ventures the opinion that "all living things and forces come from matter, and the student of the material sciences will wrest from theology the entire domain of cosmological theory." Herbert Spencer remarks, however, that "those to whom the natural genesis of simple phenomena have been made manifest, still believe in the supernatural genesis of phenomena which cannot have their causes readily traced."

Even conceding to science the truly wonderful progress it has made, it must withal confess that it has learned only the barest attributes of life, and little else. "Life, then, is confessed even by science to be a mystery, a terra incognita, bounded on one side at least by matter, brute matter, but on the other side by something, as it seems to me, finer and better than Professor Tyndall's 'streaks of morning cloud' and 'infinite azure.'" The more of the attributes of life that we are allowed to learn the greater must become the conception of our ignorance of the subject, as if the limit of ignorance was never to be reached. The sum of our knowledge of life may be compared to the apex of a triangle, and our ignorance to the limiting lines which spread out and diverge even to infinity. "Life," says Herbert Spencer, "is a continuous adjustment of internal relations to external relations."

Probably the best definition, or rather a delimitation, of life is by means of death—at least that is, in the mortal sense, as far as is apparent to our senses, more easy of conception. Scientifically speaking, however, we are not only in the dark as to the origin and nature of life but even in respect to its termination. We can tell with moral certainty when the corporeal, systemic, or somatic life ends, broadly speaking, when it ceases to functionate, but when the individual microscopic components or cells of the body die, is another and much more difficult question to answer. Animal experimentations have demonstrated that individual tissues live longer than the bodies of which they may even be the most vital parts. The hearts of the lower animals can be made to beat a long time after the death of these animals, and even after the hearts have been removed from the bodies. A muscle removed from a frog's leg can be made to contract and lift a weight, as in life, by electrical stimulation of the muscle itself or of its attached nerve. The vitality of this muscle-nerve preparation continues to diminish as time goes on, yet under favorable conditions created by imitating the natural conditions—as well as human beings can—such as warmth, moisture, maintaining in isotonic solutions, etc., it can be prolonged for a considerable period. The molecular or cellular life-activity of the body has been extended, though the parent body lies functionless.

But science is not satisfied. It has gone much further. Not only does it prolong the cellular life of the body tissues, but it grows and cultivates these cells—that is, it makes them increase their number. The significance of this accomplishment must, however, not be overestimated. It is in no sense a creation of life. It is nothing more than a stimulation of life already in existence to renewed activity. On the other hand, the possibilities of this power to grow tissue can never be overestimated. It has a practical use in stimulating the growth of the tissue cells of injured parts of the body, beyond the usual capabilities of injured tissues. In this way it is possible to shorten appreciably the period of healing. To what ultimate extent this power will be of use to mankind is hard to predict, except to say that in the nature of things this must find its niche in the economy of life.

The Evolution of Man.—Now, as concerns life itself, as it is without regard to its nature or its origin, we usually consider it to have inception at the moment of birth, although all of us know that there is life before birth—from the moment of conception, in fact. Even to place conception as the beginning of life is not satisfactory, since that would not explain the existent variations due to prenatal, racial, or disease influences. Without these variations each human being must be exactly like every other human being. It is true that the variations are not such as to effect the predominating characteristics which relegate us to certain races. These characteristics are uniform in all of our kind or "species." The life and form of the present being have origin in the parents—whose characteristics they possess; the parents themselves possess the characteristics of the grandparents—and so on with certain variations to the beginning of mankind whenever or wherever that was, even to the very genesis. A life, then, has been coming down to us for ages. Each life and being is an infinite number of years old, whether at all times in the present form, or previously in some form different from the present, or in a form bearing no resemblance to the mankind of the present time. This conception of the age of a life parallels the theological conception of the immortality of the soul. When we endeavor to inquire how far back it is possible to trace the mortal form of man, and what is his relation to other forms or beings on this earth, we are brought face to face with the theories on the evolution of mankind from lower forms of animal life.

The proposition is simply this: Did man always possess the morphological characteristics he now has? Or, tracing him back, do we find him having different bodily form and character, but having shaped himself into his present image by changing continually under environmental, or perhaps other conditions, that is, through evolution? Lamarck is the pioneer in the exposition of the doctrine of the evolution of man. "Lamarckism" first saw the light as late as 1809, and it was not until forty-nine years later, in 1858, that Darwin published his now famous "Origin of Species." This marked the beginning of the now nearly universally adopted doctrine. The doctrine itself has undergone many modifications. We now have Neo-Lamarckism, Neo-Darwinism, etc. The principle is the same in all of them.

The doctrine of the evolution of man is, then, the natural result of speculation into the reasons for the similarities in man and in some of the lower animals, with respect to certain physical and functional characteristics. The doctrine is founded on the fact that certain organs are in a rudimentary and non-functionating condition in man, while in some of the lower animals they are fully useful and active organs. Likewise, certain parts of the human body are retrograde in their form, but fully developed in the lower animals. The former condition is illustrated by the appendix, which is apparently useless in man, but is a useful organ in the lower animals. The latter condition is illustrated by the rudiments of a tail at the bottom of the spine of man. Such facts as these formed the groundwork for the inquiry into the ancestry of man, and was complete with the work of tracing man back to his very earliest ancestry, accomplished by following successively his genealogy through animals most nearly like him. In other words, this established man's line of descent.

The Descent of Man.—The animal nearest to man in morphological characteristics is the monkey, especially the ape type. Of the many species of monkeys it is found that the lower ones differ from the higher or man-like monkeys to a greater extent than man himself differs from these higher apes. On this condition of facts Huxley propounded the dictum that, "Whatever system of organs be studied the comparison of their modifications in the ape series leads one to the same result—that the structural differences which separate man from the gorilla or the chimpanzee are not so great as those which separate the gorilla from the lower apes." In tracing the lower apes back we find them approaching in form still other and non-ape animals. Each backward step is accompanied by the loss of some of the features of the higher types, and the assumption of those of the lower; and so on till the animals reached become very primitive, somewhat in this order: monkey, higher mammals, lower mammals, reptiles, fishes, insectoids, and on to the single-celled, or ameba-like creatures. This genealogical table may perhaps be evolved by commencing with the lowest forms of life and tracing them upward to man.

To clarify fully the genealogical relationship between man and his lower ancestry, it must be understood that all animal life, human or otherwise, begins in a single minute egg-like cell about 1 400 inch in diameter. The human egg or ovum, the earliest and most immature manifestation of the human being which it is to develop, is yet very like, in size and form, the mature, fully developed ameba—a unicellular being of the lowest species in the animal creation. The later, more mature, stages of the human embryo are the prototypes of mature being of successively higher species. This parallelism of human development can be traced alongside of the genealogical table already outlined, and is the basis for the doctrine of the descent of man from the very lowest form of life. In 1811 Meckel summed up these truths when he said: "There is no good physiologist who has not been struck by the observation that the original form of all organisms is one and the same, and that out of this form all the lowest as well as the highest are developed in such a manner that the latter pass through the permanent forms of the former as transitory stages."

For a long time, however, this chain of evolution was not complete, because the gap between the higher apes and man was still too wide. There was a link missing in the chain between man and monkey. In 1886 Ernst Haeckel formulated a description of the species that would, when found, fill in this gap. He called this species the "hypothetical genus *Pithecanthropus*, species *Alalus*." And, truly, in 1894, Dr. Eugene Dubois confirmed this prophesy by discovering in Java the remains of a being which dovetailed into the place between man and the higher ape—the so-called "missing link." Now the chain is complete. "Either all the various species of animals and plants have been created independently by supernatural forces (and in this case the creation of man is also a miracle), or the species have been produced in the natural way by transmutation, by adaptation, and progressive heredity (and in this case man is also descended from the other vertebrates, and immediately from the series of primates—monkeys)."

Natural Selection.—The question now arises what forces compelled the changes operating in the development of man from his most primitive

state as a unicellular organism, through the various species, to his present height as Man? The answer is, the forces embraced in *variation, adaptation,* and *natural selection.* This means that every species of animal or plant has variations within certain limits, which, however, are usually not marked enough to excite notice. But such variations which are more in accord with, or suited to, the needs of the environment and its influences, have a tendency to predominate in degree, and to develop to higher perfection, while other variations not so suited have a tendency to lag behind and to be finally wiped out entirely. The changes thus effected are then marked enough to consider the species to have changed. In the same way, the species themselves that are unsuited to or cannot meet changing or adverse environmental conditions are wiped out, leaving only the changed and stronger species to thrive and to propagate their kind. This, too, is the doctrine of the *"survival of the fittest."* The only species that survive for higher development are those that have within themselves some resistant quality that saves them from succumbing to adversity. These seem to be selected by Nature, of all others, to remain. This is in effect, then, the doctrine of *"natural selection."* The variations, the adaptations, and the natural selections are repeated in the successive higher generations or species, till it has now reached man—and will no doubt continue to perfection, if that is ever possible.

more adverse, and the more numerous become the influences with which the species have to contend the more tendency there is to variation and natural selection in order to meet them. The less adversity the less variation and the more uniformity. For this reason there is more uniformity in savages than in the civilized. The civilized have such a multiplicity of circumstances and adversities to combat that their many variations and adaptations are purposed to meet them all. The environment of civilization is continually becoming more exacting, which will require more effort or effortive-selection to meet. Only the fittest will be selected by Nature to remain and overcome these conditions. We may be unable to foretell what will take place in the environment or in the conditions of future times, but we can perceive that whatever they will be, man much change according to the needs, or else succumb as a species. The changes in us are not quite so gradual but what we can appreciate that we are even now undergoing changes which make us just a little different from our immediate predecessors in the fields of activity—in life. At the present time, as it must surely have been in the early evolutionary times, competition is very keen, and since Nature selects for survival only the best, it becomes apparent that the need for evolving a race sufficiently virile and efficient, both mentally and physically, is a practical as well as a scientific consideration.

While most of us have accepted the theories of evolution as at least logical, some very eminent scientists have denounced them as absurd. Chief among the doubters and scoffers was that eminent German scientist, Virchow. "It is quite certain," he said, "that man is not descended of apes. Man may as well be descended from the elephant or from the sheep as from the ape." Virchow's disbelief of the doctrine of evolution has always been a source of mystery to his admirers. To Ernst Haeckel is credited the remark that: "No general problem in zoology and botany, in anatomy or physiology can be discussed without the questions arising, 'How has this problem originated?' 'What are the real causes of development?'" Huxley says of the theory of evolution: "This is the question of questions for mankind. Whence our race has come, what are the limits of our power over Nature, and of Nature over us—to what are we tending? These are the problems which present themselves anew with undiminished interest to every man born into this world. Our theory that man is descended from the lower vertebrates, and immediately from the apes or primates, is a case of special deduction, which follows with absolute certainty from the general induction of the theory of descent."

Heredity.—Now, then, the whole theory of evolution, which traced the genealogy of man from a unicellular organism, dealt with him only up to the time when he assumed the image or species, Man. Discarding from further consideration man's animal ancestry, we must consider the human species itself, its characteristics, qualities, propensities, etc., but especially the manner of their acquisition and transmission, *i.e.* his heredity. Special weight has been given to this subject of heredity since the rise of interest in the science of eügenics, a science that purports to occupy itself with breeding of a better race of people, and the nurture of desirable racial qualities. It is by heredity or by hereditary transmission that we are endowed with our racial, familial, or individual character, featural or even social, our defects, and at times even our diseases. Indeed, the heredity of mental disease and defect seems to be established since the better understanding of the principles of heredity.

The theory of heredity becomes comprehensive after a brief survey of the early, microscopic, stages of the development of the human embryo. Essentially, both the male and the female elements comprise a cell body and a central speck or nucleus. The female contribution, the ovum, the human egg, so to speak, when fertilized is a minute spherical or egg-shaped body about 1/400 inch in diameter. Within is a similarly shaped but smaller body, the nucleus. Immediately after fertilization the ovum divides into daughter cells. This division continues and increases the number of cells until a mass of cells are formed which, arranging themselves into three long layers, form the groundwork for the development of every part of the body. These layers contain, therefore, in miniature every organ or member of the mature individual.

The nuclei of the male and the female cell elements each surround, graphically speaking, four minute parallel bands, the *chromatin* elements. These contain, or perhaps are themselves, the determining factors of the particular type of being from which they sprang. They determine the character of the being they are to help form. Indeed, the union of the male and the female cell elements, cell conjugation, has for its chief purpose the mixture of these chromatin elements in order to form the conjugates of these cells. This mixture of the chromatin elements is also spoken of as *amphimixis.* The term has an important bearing in the evolving of the Mendelian doctrine, to be explained presently.

But while the male and the female cell elements each contain four chromatin bodies, the fertilized ovum after amphimixis has only four because in the scheme of development four are thrown from

the fertilized ovum, just before it begins its cycle of development. The fertilized ovum contains then, two chromatin elements of each parent; each grandparent contributes one-fourth of them, each great grandparent contributes one-eighth, and so on in a lessening proportion to the remotest ancestry. Every ancestor contributes his or her proportion of the characteristics of the present individual. The mixtures and the ancestral contributions do not, of course, take place in the exact proportions mentioned. Various conditions influence the manner of the transmission of characteristics, and influence the proportion and the character of the ancestral contributions, as we shall see. The throwing off of the extra chromatin elements is believed to have for its purpose the eradication of such of the characteristics as are possessed by one parent only, and in this way to prevent wanderings too far from the prevailing species. But characteristics possessed by both parents, whether desirable or no, are emphasized, because the throwing off of the extra elements leaves remaining ones more room for self-assertion. They are left in a more concentrated, and hence in a more emphatic state.

We have seen that the union of the fertilization of the male and the female cell elements, the amphimixis of the chromatin bodies of the nuclei, starts the cycle of development of the human being. Every feature or character present in the child just born existed in miniature in the fertilized ovum as a physical imprint. The ovum is not merely the prototype in gross of the parent cell specie, but in addition it has all the individual characteristics of the whole line of parent cells, with such variations and modifications as might be expected to result from the mixture of traits of the whole line of ancestry. In other words, this is an enunciation of the doctrine of heredity. "Whatever a man may be at any particular time he is the product of the contributions of his ancestors, which he brings into the world with him, and the effects upon him of the environment in which he finds himself." Heredity on the one hand, environment on the other hand, are the factors in the shaping of our lives and those of the future. It is of vital and practical importance to us particularly, and to the race in general, that we possess by heredity, and acquire by proper environmental conditions, the best possible characteristics for transmission to posterity. Throughout this entire discussion on heredity the fact must be borne in mind that we are dealing in matters almost entirely theoretical, which have thus far no actual demonstration. The scheme of action in Nature is undoubtedly more complicated than outlined.

Racial Incest.—We have all observed the featural differences in members of the same family, and we may have been at loss to account for it. A family may have members in it who are neither like each other nor like a "composite" of their parents, nor like either one of them separately. Some take after the father, others after the mother, and some even after certain of their collateral relatives. In the same family may be blonds, brunettes, tall and short individuals, and so on, with other characteristics. In spite of the variations all yet conform to the race-type to which they belong. Northern European races are tall of stature and light of hair with blue eyes; the Southern are small, dark haired, and dark eyed. Marked variations from the prevailing type arouse a suspicion of intermixture between the races in the immediate or remote ancestry. Crossings between distinctly different races, as between white and black, white and red, etc., seems productive of transition types, for what reason is not understood, which are not as stable as either of the parent types. Mixtures of this kind are extremely undesirable from the viewpoint of racial integrity.

In like manner, a strict adherence to breeding only within the particular race and line, inbreeding, or racial incest, as it may be called, is undesirable in man as well as in animals. It is universally recognized that actual or familial incest is undesirable, and that such unions almost invariably result in defective lineage. That form of incest is abhorrent to our notions of civilization, is not permitted, and, therefore, needs no further attention. Intermarriage or inbreeding not merely within the race but also within the tribe, while it may result in the production of a highly specialized and sensitive nervous organization, which is, however, very prone to rapid disorganization, more often produces poor physical types. For this reason it is nearly as undesirable as cross-breedings of wide latitude. The best breeding is within the race but between the tribes. The term "tribes" is here used to denote, say, the different subraces, as the different white races, for example. Unfortunately, the domain of this entire subject is as yet little understood.

The Mendelian Doctrine.—In an effort to explain these familial differences and similarities, Gregory Mendel, an Austrian monk, established by experimentation with plants a mathematically accurate scheme of the hereditary transmission of qualities. This scheme or doctrine is now known as the Mendelian Doctrine, or Mendelism. Whatever application of this doctrine is made in man, it must be borne in mind that Mendel worked entirely with plants. Yet even in man many heretofore inexplicable phenomena of heredity find explanation under this doctrine. Mendel cross-bred variously sized and variously colored peas and observed the nature of the ensuing progeny. When, for example, he crossed tall plants with short ones, or white ones with red ones, he invariably found that the issue were three tall, or three red, to one short or one white plant, and so on when plants with other characteristics were crossed. The most desired or the fittest quality in a plant he called a "dominant," as would, for instance, be exemplified by tall plants; the undesirable qualities, here personified in a shortness of the plants, he called "recessive." Mendel's scheme evolved the details of the variations in the kind of offspring that resulted from the union between a dominant and a recessive.

The elaboration of the doctrine credits the germinating cell elements with having within themselves the materials which determine the character of the being they form. These entities are called "*determiners.*" "These determiners are definite material entities, and therefore the inheritance of these special characters cannot be blended inheritance, but must be an inheritance dependent upon the segregation and grouping of these determiners, and Mendel endeavored to formulate with mathematical precision the ways in which inheritance would manifest itself, by determining all the possible combinations in which the determiners could group themselves." A limit of six possible combinations are provided for in this doctrine.

Every dominant or recessive offspring, the issue of a dominant and a recessive parent, have dormant

within themselves the desirable or the undesirable qualities, as the case may be, possessed by the parent. The recessive progeny have within themselves, in a dormant or inactive state, the dominant qualities of the dominant parent. Conversely, the dominant progeny have within themselves, in a dormant or inactive state, the undesirable qualities of their undesirable or recessive parent. Though inactive in this offspring subsequent unions with other types, or under the influence of conditions not yet understood, may activate the dormant qualities in the descendants.

To apply this scheme to human beings let us call a perfectly normal, healthy individual a "dominant," and a defective individual, defective in some way or in some respect, a "recessive." Schematically carried out the union of such individuals must result in three normal and one defective offspring. The difficulty of the application of the scheme to human beings lies in the fact that Mendel dealt with plants and that he had to have series of four offsprings at least, while in man the total number of offspring may be less than the schematic four. Now, the dominant or normal children of such a union would have in their composition a recessive characteristic, dormant in them, however; the defective child would, on the contrary, have dormant within itself a dominant characteristic. In future generations, under certain influences, the characteristics now the dormant ones may become the active ones. In this way the normal children may in their unions, and even if they unite with other normals, yet have one or more recessive children. On the other hand, the defective child, if his offspring numbers less than the schematic four, after union with a normal, may have only normal children; that is, only the dominants of his future family may be born. The absence of any subsequent births prevents the assertion of the defective stock of this union. The active recessive element in this family is wiped out because of the limitation in the number of the offspring. This becomes the explanation for the heretofore curious fact that in a family of children, the issue of highly developed parents, there is born a defective. In all likelihood, if the ancestral history of this family were traced back there would be discovered somewhere in the stock from which this child came a defective ancestor. In the defectives resulting from racial or familial incest no fitter determiners are brought to the stock to raise it and even slight racial or familial defects become emphasized from the mere addition. In any event the study of the stocks of prospective mates might reveal interesting information about defective ancestry, when it would otherwise not be suspected.

Eugenics.—It is the sphere of eugenics to study the stock from which individuals spring. Then, it is the ideal of the eugenist to mate only individuals of the best stocks—to mate them also with the view of bringing out particular desirable qualities. For this reason the science of eugenics is also called "Stirpiculture," from the Latin *Stirpes*, stock. Animal breeders are interested in this same endeavor, and we need not be prejudiced against this science because of its application to animals. Human beings are animals, and not far distant from the lower ones, as we have already seen. Herbert Spencer aptly remarked: "To be good animals is the first requisite to success in life, and to be a nation of good animals is the first condition to national prosperity."

Eugenics is either positive or negative. Positive eugenics concerns itself in the building up synthetically, so to speak, of a better race. It is the stock-farm method. Negative eugenics is that phase of this science which desires to prevent the breeding of defectives by preventing the mating of defectives. At present this promises to be the most practical way, since, for obvious reasons, the stock-farm method cannot yet be applied to human beings. Eugenists propose to render sterile the physical defective and the criminal defective, and thus to prevent the propagation of such strains. But many public spirited and race proud people oppose this plan of sterilization on the ground that a defective may yet, in a union with a normal, propagate *some* normal children whom we have no right to prevent from coming into being—in order to prevent the birth of those that might be defective. This may have some justice when we consider that the unions of normals with "tainted" ancestry may result in defective offspring just as much as after the union of known defectives. It seems that this is altogether too theoretical and sentimental an objection for so practical a problem as this one. Many States have, however, already passed laws requiring the sterilization of criminals and defectives in the public institutions.

To illustrate the possibilities of negative eugenics and to point out an interesting example of the schematic tendency to the hereditary transmission of defective qualities, let us consider the so-called "bleeders." These individuals bleed very profusely, sometimes even fatally, from insignificant wounds or abrasions. Surgical operations are out of the question with them, and death may frequently result from inability to perform on them urgent surgical operations. Investigation demonstrates that this bleeding characteristic is transmitted in a definite manner, from the bleeder *through the female* offspring only, without, however, affecting her, to her male issue. It skirts all the immediate offspring of the bleeder and affects only the *male* grandchild through the female. The bleeding characteristic was, then, dormant in the first generation, but activated in the second generation through the female. Hence if the original bleeder had no female children the tendency would be entirely wiped out. But, unfortunately, sex determination or influence is not within our knowledge. It is easy of conception, however, that other defects have some natural, and as in bleeders, some definite scheme of transmission, which were it possible to determine, say on Mendelian principles, would put the breeding of human beings on a scientific basis.

The attempt to build up a better race of people synthetically by selecting the best material mentally and physically, and the prevention of propagation of and by defectives are but preliminary steps in this question of eugenics. Since a very large part of defective characteristics transmitted are acquired primarily through disease, it is of paramount importance to the eugenist in his endeavors, to prevent the acquisition of diseases, so that there may be none to spread and none to transmit. It is the *nurture* as well as the nature of racial qualities with which the eugenists are concerned. It was formerly strongly believed that all diseases were transmitted. Now this is modified somewhat. It is believed that the germinating cells of the body become sensitized to, and weakened by the particular disease from which the

parent is suffering. The offspring, while not actually suffering from the disease, is said to be predisposed to that disease, which he may acquire under certain adverse environmental conditions. But disease can be warded off by obtaining for the individual with this predisposition the best possible environment. This is illustrated in the offspring of tuberculous parents, who do not themselves have the disease at birth, and who need never acquire it if taken from the tuberculous environment of the parent and placed in the best possible antituberculous environment. On the other hand, if the disease affecting the parent is not too profound, or is not of sufficient duration to leave an impression, the germinating cells of the parent body are not sensitized sufficiently to transmit a predisposition. The deleterious influences of ancestors generations back are felt by the present generation, and the biblical prophesy of the visitation of the sins of the parents on the children of future generations is none too lightly carried out. Individuals defective through defective ancestry are just as helpless as the individuals whose defects are of present origin. They are enormous burdens on the State, and a drain on the coffers of the taxpayers. The large number of physically and mentally feeble persons is a growing menace to the community, and fully justifies the interest taken in this problem of eugenics. Proper ancestry is a very essential factor in the wellbeing of the present generations. Indeed, we have an absolute right to good ancestry. Emerson said that "a child's education begins a hundred years before it is born." He may well have said, "thousands." It begins with the remotest human ancestor and continues throughout the life of the child in question.

Having considered the details of man's animal ancestry, his human ancestry, and the principles of heredity, we are now well launched upon the consideration of man's sphere on earth from birth —and even before birth—throughout life, and to death.

Child Life.—In early historic times a child's individuality began only when it was in being—that is, after birth. Even then its life or its welfare was of little concern. A child was the exclusive property of the parents, to be dealt with as they saw fit. They could take its life with impunity. There was no communal interest in the child. Now the State is considered to have as much interest in the child as the parents, possibly more. In early times infanticide was a common and a not reprehensible crime. In ancient Greece they were wont to expose to the elements such of their children as they believed were not robust enough to become warriors, and thus good citizens. This is probably the first sign of the doctrine of so-called euthanasia, the killing of the defective and the sick, of which we now hear so much. In ancient Rome infanticide was advocated as a legitimate means of limiting overpopulation. Pliny, the elder, speaks of this practice with approval. Be it said, however, to the credit of early writers of equal note, that they expressed their profound abhorrence of this practice. In like manner, as is to be expected, the destruction of life before birth was very common.

Now, although we consider the lives of children just as sacred as those of adults, even we need some moral education on the sacredness of life before birth, and even before that. The antiracesuicidists justly contend that no amount of sophistry can justify the prevention of the coming into being of human life at any stage, unless we deny at the same time absolutely the inviolability of human life. If ever justified, it is justified only to save an existing prior life—the life of the mother. Children born to unwilling parents are the only really and morally illegitimate children. Overpopulation among the poverty stricken is a problem which must find solution along other lines, in all likelihood along economic and social lines of betterment. The Malthusian method of regulating and checking overpopulation, proposed by the Rev. Thomas Malthus (1766-1834), consisted in deferring marriage till late in life. This proposition has now no moral significance, although it seems that the increasing stringency of life under present keen competitive conditions and with respect to the cost of living is accomplishing this very result.

The decline in the birth rate is among the higher and the more educated; the increase is among the lower. This is not desirable, since the elevation of the succeeding generations of higher classed individuals, were they sufficiently prolific, could be continued from the point where the preceding generations left off, and thus progress among a large body of people would be very rapid. The education of the lower classes must always be along primitive lines. In sufficient numbers the former would tend to predominate and survive as the fittest. Poverty and large families seem, however, to be inseparable. "Wherever there is a greater carelessness of child life, in the matter of its use, there is the birth rate highest." David Heron found, on the contrary, that before the economic legislation against child labor in the woolen districts of Yorkshire, England, large families were very common, were economic assets, because of the use of child labor, and their health was carefully guarded for that very reason. Since the restrictions placed on child labor there are few districts where prenatal life destruction is so consistently carried out. Investigations of child labor in the Southern States of the United States, although as yet incomplete, point to the same conditions. In these places it is either the mothers or the children who must work in the factories. The question which is yet to be answered is whether it is more harmful for the child, in respect to its physical and mental wellbeing, that the child itself should work, or that its mother should work. Neither is desirable in itself. Which is the lesser of the evils? Which affects infant mortality least?

Infant Mortality.—The question of the reduction of infant mortality now commands considerable attention, not only from moral or sentimental grounds, or from instinct which creates a desire to save the lives of our own kind, but also from the more modern economic standpoint. Children are subject to a great many diseases because their tissues are more tender, are yet not sufficiently hardened to make uninviting food for the disease agencies. Scientific and hygienic advances have reduced the infant mortality from nearly every disease to a very large extent. There is yet so much room for improvement, however, that the time for congratulation has not yet arrived. Diseases of infancy and childhood are now prevented rather than cured. This is the Golden Age of preventive medicine. All the time and money formerly wasted in cures, or to be more exact, in funerals, can now be devoted to child welfare in other directions. One-fifth of all children still die before the first year; one-half before the twenty-third. What does it cost to keep

these children alive in this unproductive period? Whatever money is thus spent is never returned to the coffers of the community, as is done by those who live through the productive period of life. In the language of the sea, it is a total loss. The cost of salvage will be many times repaid by the productive value of those salved. Every baby born into this world now has a better chance to live through adolescence than ever before. In time the State will pay at least as much attention to the lives and welfare of children as it already does to those of animals. It must only appreciate their money value. The conservation of child life must soon be a branch of economics, in which science will do the field work, the State the executive work.

The Conservation of Life.—The movement for the conservation of child life is only a part of the general movement to conserve and prolong life through the prevention of disease and the betterment of economic and social conditions. Scientific researches and active hygienic measures have committed severe depredations among the disease forces. A little retrospect will bring to mind the fact that the occurrence of plague, cholera, smallpox, etc., which swept away whole communities and decimated the population of whole nations, is still modern history. These diseases are today so rare that few physicians ever have an opportunity to see any of them. It is within memory when the Southern States were hot-beds of yellow fever. It is gone, probably never to return. Systematic antiplague work drove that disease out of San Francisco. The few sporadic cases in Porto Rico, Cuba, and New Orleans mark the end of these diseases in the civilized and scientifically controlled countries. The eradication of these diseases have, however, not been accomplished without the making of many medical martyrs.

The progress made in the reduction of such diseases as typhoid fever, cancer, and the degenerative diseases gives little room for pride. Cancer and the degenerative diseases, such as hardening of the arteries, kidney, liver diseases, and the like, are on the increase. While typhoid fever has shown a reduction of over 40 per cent. since 1880, cancer has risen over 105 per cent. Typhoid fever is now being further reduced, and, it is hoped, will be eradicated entirely by the introduction of typhoid vaccination. Against the spread of cancer a campaign of public education has been started to teach the public the probable predisposing causes, the earliest signs of the disease, and the necessity of obtaining expert advice at the earliest possible moment. The increase in the statistical cancer population is attributed by many merely to refinements in diagnosis, which discovers many cases that were not previously discovered. The increase is said to be more apparent than real.

With tuberculosis we have had the campaign of education idea developed to the highest degree. And who can say that the results have not been more than gratifying? The omnipresent skeptic even in the medical profession denies a reduction in the amount of tuberculosis. When it is considered, however, that modern methods of diagnosis make possible the detection of this disease almost before there are any outward manifestations, and that even with the addition of these unmanifested types the disease is certainly not claimed to be on the increase even by these skeptics, then it must be apparent that there has been a very material reduction. Progress with this disease is made not so much with the reduction of the numerical tuberculous population of any one period or of any one place, as it is in the arrest in the advance of this disease, and the prevention of its spread among heretofore healthy individuals. It is better for the community to recognize every case at its inception and to admit a rise in the number of the afflicted, than to be satisfied with an apparent decrease because all cases had not been discovered till so far advanced as to be without hope of recovery. There may be an increase in the number of incipient cases of tuberculosis. That is because they are recognized in that stage. But the advanced cases show a steady decrease in proportion as the incipient cases rise.

The terror inspired by tuberculosis has almost disappeared, because it is generally understood that early diagnosis with proper care means certain and speedy cure. The number of totally cured cases, preaching the Gospel of modern methods of combating this disease, is increasing daily. A diagnosis of tuberculosis no longer means a death sentence.

Economic Value of Life.—Previously the death rate was extremely high in childhood, and a little lower in adult life. Now it seems to be reversed. The seeming increase in the mortality of adults is ascribed merely to the general lengthening of life, which permits more individuals to get into the adult class before they die.

The prolongation of life can be accomplished only by advances in preventive medicine. Professor Rosenau of Harvard University remarks: "Preventive medicine is the watchword of the hour, and enlistment in the cause can come only through education." Another expert remarks: "The highest aim of scientific medicine today is the eradication of preventable diseases, and in the solution of this problem all men who have the interest of the human race at heart can and do unite, regardless of medical schools and creeds."

Except for the few large generous private donations to this cause, there has been little support from the public at large, and only meager contributions from the State. For example, in the last few years, the city of New York spent about 150 millions of dollars for the governing of that city. For its health it spent about 3 millions. For its fire department it spent over 8 millions, though its total fire loss was a little over 9 millions. During the same period over 33,000 lives were lost from preventable causes. With the value of a life placed at $1,700, the loss is above 55 millions of dollars. Offset this against the 3 millions spent in health work. This is the story of all State appropriations for health work. Far more money is appropriated for the protection of the lives and of the health of cattle. Ex-President Taft answered objections to health appropriations by saying: "There is nothing in the constitution especially about hogs or cattle or horses; and if out of the public treasury at Washington we can establish a department for that purpose, it does not seem to me to be a long step or stretch of logic to say that we have the power to spend money in a bureau to tell how we can develop good men and good women."

Prof. Irving Fisher of Yale remarks: "If we appraise each life lost at $1,700, and the average earning capacity at $700, the economic gain to be obtained from preventable or postponable disease, measured in dollars, exceeds one and one-half billions annually."

Longevity.—In spite of the myth of Methusala and other myths of the ancient long-lived, it is modern civilization that has prolonged the span of life. During the Dark Ages, when disease ravaged the weak, and war destroyed the strong, the average length of life did not exceed 12 years. For the good of the race it seems that pestilence, since it destroys the weak, is a boon to the race—a sort of providential euthanasia—while war, since it destroys the strong, undermines the racial stability. At present the average span of life is 45 years. If the sunny optimists have their way, but especially if science has free rein, it promises to be prolonged even more.

Karl Pearson's investigations on longevity point to hereditary influences even in this matter. He found that of children born of mothers who died before the age of 39, 68 per cent. died before the age of 21; while of children born of parents reaching the ages of 70, less than 30 per cent. died before 21.

It is not merely the prolongation of life in the abstract that is so much to be desired. It must be on a concrete basis of efficiency before it can be of value to the community or to the individual. "It matters not how long we live, but how." A long life, but an inefficient one is no life at all. Longevity associated with mental or physical invalidism is deplorable. The length of life must be prolonged only in company with the active efficiency of that life. As E. E. Rittenhouse, of the Equitable Life Insurance Society, puts it: "Efficiency longevity is best achieved by bearing in mind the principle that life is a trust fund, which should neither be hoarded with parsimonious and sterile solicitude, nor expended with lavish and futile extravagance."

Old age is either chronological or physical. Physical old age may occur when the years are still few. It is due to disease or dissipation. Physical old age is premature old age. The creative power of the mind ceases at 45, and if the mental faculties have not been developed before that time, there is little possibility for active development after that time. The prematurely senile attain this maximum of mental development even before 45. Their general incapacity sets in at a very early age. A man may acquire a fund of knowledge after 45, but only such matter can be assimilated as requires no creative activity to absorb. The very quietude of the mind after this age allows the orderly and systematic arrangement and storing of knowledge already therein. The bustling activity of youth, in mind as well as in body, does not brook such arrangement of knowledge. The properly arranged library of knowledge of the aged can be drawn upon by those who have not lived long enough to store in their own pile. This, then, is the experience of age which is of so much value to youth. Experience is nothing more than an orderly arrangement of knowledge already acquired. It is "old men for council, young men for war." Dr. Osler's remarks on the subject of the usefulness, misquoted "uselessness," of age are: "The teacher's life should have three periods—study until 25, investigation till 40, profession until 60, at which time I would have him retired at double allowance. Whether Anthony Trollope's suggestion of a college and chloroform should be carried out or not I have become a little dubious, as my own time is getting so short."

While it is true that many of the most responsible positions are held by men advanced in years, it is quite as true that they hold their positions not so much because of any present active creative ability, but because, having advanced to these positions by years of activity, they now hold on to their positions by force of might, so to speak. More especially do they hold on because they are in possession of a fund of knowledge piled up during these years, and possessed by no one else. The presence of creative mentality in youth only, is tacitly admitted by the great employers of labor who refuse to give emplomeut to individuals beyond 45. Government, military, and other similar organizations recognize this and provide for compulsory retirement after a certain age, and this age is always descending.

Old age which has not stored up its fund of knowledge and conserved its bodily vitality is of little use, and might as well be "chloroformed," to quote as they misquote Osler. On the other hand, many old men clog the wheels of progress by persisting in the occupancy of positions which, although they have deservedly conquered, they have outgrown, and which positions they would do well to relinquish to younger, more active, and more progressive assistants. It is a question whether such individuals are not as undesirable in the economy of life as those who have never created, and who in their old age are dependent on others. Every person, no matter what is his position in society, should make such provisions for the period of incapacity from old age, that he will be a burden on no one; that the offspring shall be at liberty to work out their own economic salvation without hamper from dependent parents. Provision for old age is surely as important as provision for family in case of death during the active productive period, that is, by life insurance.

Life Insurance.—The necessity for life insurance is no longer questioned. It is an established institution in civilized communities. The computations with respect to life insurance premiums and policies are made from the expectancy of life as is shown by the so-called life or mortality tables. Life insurance policies are really wagering contracts. The insurers wager an amount of money on the possibility that the insured will live beyond the time when the premiums paid will have paid for the loss sustained by the death of the insured. The longer the insured lives the less will the insurers lose—in the long run, the policyholders. It is for this reason that a great deal of the campaigning in the interest of longer life, the prevention of disease, emanates from life insurance organizations. They supply free nursing to their policyholders, establish sanatoria, print and distribute literature on the many phases of disease prevention, etc. They are doing part of the work that should be done by the public at large.

While life insurance is the method of providing for one's dependents in the event of death, annuities are designed to make financial provision during old age. It is the reverse of life insurance. In the latter period premiums are paid for the return of a lump sum in case of death. With annuities a lump sum is paid and periodic payments are made throughout life, the size of the annuities varying according to the sum paid, just as the size of the life insurance benefit varies according to the size of the premiums.

The construction of life tables is based on the registers of the vital statistics for certain periods and from certain districts. From these registers

the expectancy of life is computed. Logarithmic calculation determines the premium that each policy-holder shall pay. The value of these tables depends entirely on the accuracy of the registers of the vital statistics. Their importance even in other regards cannot be underestimated. Large communities are daily aiming to perfect their registers; in small communities they are deplorably inaccurate. The accuracy of the registers of a community is a good index of that community's caliber.

Death.—We say, unknowingly, however, that there is an end to everything. Life ends with death. But life is matter, and as such is indestructible. In the sense that man is constantly reproducing himself, life is continuous, without end. Each new life is in being before the old one goes out of existence. To most of us the fact of the death of the body is simple. Yet it is far from simple to tell definitely the moment of death. Treatises have been written on the signs of death—and the question is still open. Man has always felt this ignorance and feared burial alive. While the possibility of this occurrence is very remote, it should yet be considered. Indeed, in animals apparent death, or hibernation, is recognized. Animals like the hedgehog, bat, bear, etc., habitant in cold and temperate zones, assume, during the cold season, a condition of suspended animation or apparent death. Their temperature is reduced to that of their surroundings, their respirations become so reduced as to be imperceptible, and they take no nourishment. On the advent of warm weather they thaw out and resume their usual activities.

Human hibernation, or trances, have been mentioned in literature from time to time. There are apparently authentic accounts given of human hibernation among the natives of India, lasting for periods of over six months. They have as yet no scientific corroboration. The subject was of sufficient interest in the middle of the last century to result in the publication of a book by Braid in 1850 on "Observation on Trances or Human Hibernation."

Conclusion.—The study of life is important, useful—it is compelling. To be thorough it should commence with a careful perusal of the origin of mankind—the doctrine of evolution. Man's evolution should be followed from unicellular organisms through insectoids, fish, reptiles, invertebrates, vertebrates, higher primates, the missing link, to man. The study of life should embrace the subject of heredity, Mendelism, and its offshoot, Eugenics. It must include the consideration of life from infancy through adult life, its conservation, prolongation, and especially the means of prolonging life activity and usefulness. It must not end before we have given thought to the money value of life to dependents and in old age and the necessity of insurance against both. Then we are ready for death—and after death—life? Who knows?

"Dust thou art, and unto
Dust shalt thou return."
Genesis, iii, 19.

351 East Fiftieth Street.

Congenital Cyanosis without Auscultatory Signs.—M. Grandjeon calls attention to a group of cases of congenital heart disease in which there are no auscultatory signs. At autopsy there is found a uniform narrowing of the pulmonary artery and an abnormal uniformity of thickness of the interventricular septum.—*Gazette des Praticiens.*

A STUDY OF 150 CASES OF TWILIGHT SLEEP.

By JACOB HELLER, M.D.,

Brooklyn, N. Y.

In considering any measure for the relief of pain incident to childbirth, two things have to be proven: (1) That the measure actually does relieve the pain, and (2) that it is free from danger to life and health of mother or child.

That opium and its derivatives, and scopolamine and the whole group to which it belongs, possess, in varying degrees, the power so to lower the sensitiveness of the nervous system as to diminish pain or abolish it, has long been an established fact, but that they can be used in combination in such manner as to rob childbirth of its terrors and render it painless or almost so, without interfering with its normal termination was first described by Steinbuchel in 1902.

It was, however, Gauss of Krönig's Klinic in Freiburg, who brought the use of scopolamine-morphine anesthesia in labor prominently before the world. It was also Gauss who gave it the convenient and very descriptive name of "Dämmerschlaf," or as we call it, "twilight sleep." His first article on the subject, which appeared in 1906 and contained a report of five hundred (500) labors in which twilight sleep was used with relief of pain and perfect safety to mother and child, created intense interest in the subject among medical men, and for a considerable time after numerous reports on the subject appeared in medical literature. Some of the writers, chief among whom were Krönig, Zweifel, Beiruti and Newell, confirmed the observations of Gauss as to its efficacy and safety. Others, particularly Hocheisen, not only denied any great benefit to it, but condemned it as unsafe and dangerous to mother and child.

As has so often been the case, however, in medical research and investigation, the adverse reports were readily accepted as final, with the result that interest in the subject subsided, and, with the exception of Freiburg, where it was adopted as a routine measure, the method was not tried anywhere to any great extent and with any degree of thoroughness.

In May of this year there appeared in a New York lay magazine a sensational article on twilight sleep which brought down upon itself the just criticism of the medical press, but which, however, served the good purpose of reawakening a general interest in the question. It was then that the medical staff of the Jewish Maternity Hospital decided to give the method another and thorough trial if possible. We say another and thorough, advisedly, for only an indifferent attempt had been previously made and abandoned for no apparent reason. We were fortunate in having been able to obtain the cooperation of Dr. Kurt E. Schlössingk, a coworker of Krönig and Gauss, who was thoroughly familiar with the Freiburg technique, mode of administration, indications, and contraindications, points so much emphasized by Gauss as essential to the successful application of this method.

Our report is based on the experience obtained in 150 cases drawn from the charity and private service of the Jewish Maternity Hospital

No case was excluded except for one of the following reasons: (1) A marked disproportion between the fetal head and pelvis, requiring in the opinion of the attending, a major obstetric operation. (2) Placenta previa. (3) Absent or doubtful fetal heart sounds. (4) The woman being too far

in labor. The last class was excluded for obvious reasons; the first three, because we did not want any accident to mother or child, under such circumstances, to be attributed to the twilight sleep. All minor degrees of pelvic contractions were included, where it was thought labor could be terminated by forceps. So also were included in this series two cases of nephritis with threatened eclampsia, one of which culminated in convulsions six hours after delivery and made a rapid and uneventful recovery, as well as two cases of chronic endocarditis. These two latter were particularly gratifying, going through their labor without any shock or strain on their hearts. It seems to us that twilight sleep is exceptionally useful in this complication.

Of the series one hundred and thirteen (113) were primiparæ and thirty-seven (37) multiparæ; one hundred and forty-eight (148) presented the vertex and two the breach. Of the vertex presentations there were the usual number of positions, thus, 103 were L.O.A., 27 R.O.P., 16 R.O.A. and 2 L.O.P.

Mode of Delivery.—Of the total of 150, 131 delivered themselves spontaneously with the ordinary support of the perineum, and 19 were artificially terminated. One by breach extraction and 18 by forceps, 3 of which were medium and 15 low. With a little more patience on the part of the attending the number of forceps deliveries could have been reduced to six, for in only six of the cases was there any indication for immediate delivery. The others were done for the convenience of the attending. Krönig lays great stress on the fact that twilight sleep reduces the percentage of forceps deliveries, for the reason that with the pain and the consequent exhaustion removed, there is no risk to let the patient take a longer time to deliver herself.

Separation of Placenta and Bleeding.—"What effect has the method on the separation of the placenta and bleeding?" is one of the questions most frequently asked. For, with absence or diminution of subjective pain, it is difficult, for one who has not watched these cases, to conceive of a well contracted uterus. In our whole series we did not meet a single instance where the placenta was retained for longer than thirty minutes, and the average time for its expulsion was about twenty minutes. Nor did we meet a single case in which bleeding was abnormally profuse. In fact, a hemorrhage which might have been expected in 150 labors was here conspicuous by its absence.

Duration of Labors.—With very few exceptions, all writers on the subject agree that labor is moderately prolonged by twilight sleep. Siegel, of Freiburg, states that in their experience there is a delay of about one hour for the first stage and thirty-three minutes for the second. Our figures on this phase are rather inconclusive and, if anything, would show a shortening of labor, for the average duration of labor in the primiparæ of the series was only 8½ hours, obviously too short. The reason for this apparent shortening is the fact that the great majority of our patients are admitted in a fairly advanced state of cervical dilatation, and our records take the time of their admission to the hospital as the time of the onset of labor. Personally, from observations made on a small number of cases that were admitted, that were not in labor, I believe the first stage is actually somewhat shortened, and I attribute that to the softening effect, morphine-narcotine meconate and scopolamine have on the cervix and lower uterine segment. The second stage, however, is positively delayed. The patient being in a semi-conscious state cannot be taught to utilize her abdominal muscles to advantage, since the contractions of the abdominal muscles are entirely of voluntary origin.

Condition of the Mother During Labor and the Puerperium.—Half an hour after the first injection the patient usually becomes flushed. The pupils are dilated and the lips parched. She is somewhat drowsy and her pains markedly diminished. With the second dose her sleep deepens and the uterine contractions are evidenced by a slightly painful expression on her face or by very weak attempt at crying. Her memory, however, is still not much impaired. It is not until after the third injection that her memory is entirely lost. She then fails to remember any object previously shown her or the number of injections given, although she will answer questions quite readily on anything that does not tax her memory. This state continues until the birth of the child, when she falls in a quiet and natural sleep lasting in our patients about three hours. She awakens rested and cheerful, free from any shock or sign of exhaustion, no matter how long the labor lasted. Often the patient asks of the nurse when she will be through with her confinement, and it has been hard to convince her that she is already through without showing her child to her and inviting her to feel her reduced abdomen. The rest of the puerperium was perfectly smooth and normal, so much so that patients were with difficulty kept in bed and many were permitted to get out on the second or third day.

The most troublesome thing encountered by us was occasional restlessness. Particularly was such the case at the beginning of our work when we were rather timid and felt our way slowly, being uncertain of the dosage and the intervals. With gained experience and confidence in the method we were able to eliminate much of the restlessness, and the latter was only rarely evidenced by the patient's moving about in bed and upsetting her aseptic surroundings.

Effect on the Child.—The harmful effects of opium and the belladonna group on infants and children being known, apprehension for the twilight child is justified. Many prospective mothers, as well as many physicians, ask the question: "Does twilight sleep have any ill effect on the child?" Of the 152 children (two of the births being twins) not one was born still, that is, failed of resuscitation. Three of the children died within a short time after birth. One, in the eighth month of gestation, with a spina bifida, died three hours after birth; a second died three days later from melena neonatorum with a family history of bleeders, and the third one apparently from subdural hemorrhage. We could obtain no postmortem to verify our assumption and so this death remains doubtful. But even if we should credit it to twilight sleep, the child mortality would be 0.6 of one per cent., comparing more than favorably with the ordinary fetal mortality of 1.5 per cent. The fetal heart *in utero*, which was always watched with the greatest care, never went up above 160 or fell below 120 per minute. One hundred and twenty of the children cried out immediately and spontaneously. In 29 there was an average delay of five minutes, and in only one case, where, owing to great restlessness of the mother, we were compelled to repeat the morphine-narcotine meconate three times, was there a delay of 20 minutes, requiring artificial respiration. This child did not do well for a week; was rather drowsy, did not take the

breast, and cried but weakly. It finally, however, made a good recovery. The comparative freedom of the child from the effects of drugs, which so overwhelm the mother, can be explained only by the selective powers of the placenta preventing the greatest part of the drug from reaching the fetal circulation.

Technique.—We followed the technique practised at Freiburg without deviation. When it was determined by the effect of the uterine contractions on the cervix and membranes, that the patient was in active labor, she was removed to a dimly lighted room away from the general noise of the hospital. She was placed in a bed prepared for delivery. After her pulse and respiration, the fetal heart, as well as the frequency and duration of the uterine contractions, were observed and noted down on record, she was given an initial injection of 1 c.c. of a 3 per cent. solution of morphine-narcotine meconate, which is equal to half a grain of the powdered drug. Through the same needle and without removing it, she was injected with 1.5 c.c. of a 3/1000 of 1 per cent. solution of scopolamine hydrobromide, equivalent to 1/133 of a grain. One hour later a second injection of scopolamine alone, one-third of the original dose, that is, one-half c.c. of the same solution, was given. Half an hour after the second injection the memory test was applied; the patient was asked whether she remembered having seen a certain object previously shown her or the number of injections given her. If her answer was ready and clear she was given another half c.c. of scopolamine at once, if not, we waited with the third injection for the hour. She was then constantly watched, and the injection of 0.5 c.c. of scopolamine repeated on the slightest sign of reappearance of memory until she was delivered. On an average the injection had to be repeated every one and one-half hours. The greatest number of injections given to any one patient was 19, the smallest, one; the average, five. The longest time a patient was in twilight sleep was 25½ hours; the shortest, 45 minutes; the average, 6½ hours. In only a few instances, owing to restlessness of the mother, did we repeat the morphine-narcotine meconate also. Pituitrin we used rather frequently, a little more often than ordinarily. With the birth of the child the cord was rapidly clamped and the child removed whenever that could be accomplished before it cried, so as not to awaken the mother.

Results.—In 122 cases, or 81.3 per cent., we succeeded in obtaining a complete amnesia and an almost equal degree of analgesia. All that occurred during the time the patient was under the influence of the drugs, was wiped out of her memory. In 13, or 8.7 per cent., we got analgesia without amnesia. These were started somewhat too late. Gauss thinks that the ideal case is one in which amnesia is complete. In our opinion, amnesia, while present in the great majority of cases, is not essential. The analgesia case without amnesia seems to us the more ideal, for not only does that labor appear more natural, but the patient can make good use of her abdominal muscles to shorten the duration of her labor.

In fifteen cases, or in 10 per cent., we failed to obtain any marked results. With our present experience it is quite possible to reduce the number of failures to a smaller figure, but since the sensitiveness of the nervous system varies in different individuals, as does the susceptibility to drugs, there will always be some cases that will not be influenced by the drugs unless carried beyond the point of safety.

Our small series, then, proves that judiciously used, and with proper precaution, the method is capable of relieving pain in 90 per cent. of cases and that it is free from any danger to life or health of mother or child.

Let me say a word about the objection raised against any attempt to relieve childbirth of pain and suffering. It is argued that since nature that encourages propagation in every possible way and manner, could not have been so cruel and inconsistent as to inflict untold suffering on half of the human race, or perhaps on half of living creation, and thus handicap her own work, if she had no distinct purpose in that pain and suffering; and that any interference with that purpose will be resented by her in some manner. Krönig tries to meet that argument by stating that a very great number of our present-day women to whom twilight sleep is particularly beneficial, are so far removed from nature as to make their labor border on the pathological, and therefore, he says, interference is not only justified but clearly indicated.

In our opinion, subjective pain incident to childbirth serves no purpose in nature but is rather an unnecessary result of an unchangeable natural law, that all severe muscular effort is accompanied by pain. The metabolic end-products of muscular activity are irritating to the nerve ends, causing pain. Thus, we see fatigue following an immoderate bodily exertion, severe pain accompanying the hurried muscular peristalsis of the bowel in ridding the system of injurious material; excruciating colic caused by the expulsion of a biliary or renal calculus, and finally agonizing pain incident to the expulsion of the fetus from the uterus, and in trying to relieve this pain we are not in conflict with a natural purpose, but with an unnecessary and undesirable result of a natural law.

PRACTICAL POINTS IN TONSILLAR INFECTION.

By BEVERLEY ROBINSON, M.D.,

NEW YORK.

There can be no doubt at the present time, in view of good, careful work on the part of experimenters and physicians, for several years, that not a few acute and chronic diseases are dependent upon tonsillar infection. Of course, in some cases, there are errors of observation, or interpretation. But in summing up numerous facts from trained observers, we should conclude that in the diseased tonsil is found the direct cause of some acute and chronic affections.

Among the former, acute arthritis, often rheumatic, seems to be the disease which accompanies or follows the affection of the tonsils most frequently. To some writers, an acute inflammation of the tonsils as of the appendix at times, indicates clearly, separately or combined, a rheumatic cause. To support this view, they note the similarity of glandular structure and also the effects of treatment. In both diseases salicin, or the salicylates, have often marked efficacy. Further, in both diseases, certain hygienic preventive measures can be utilized effectively. These are mainly included in proper habits and dietary. Avoidance of dampness, draughts, badly ventilated, crowded places on the one hand, and on the other, a suitable vegetarian

diet with moderation as to meats, sweets, rich food, will do much to ward off attacks. Local measures cannot be the same by reason of difference of locality as to tonsils and appendix, but even in this regard, certain topical applications may be usefully employed which are not unlike, although their way of relief in the two diseases is not the same.

The tincture of iodine, pure or diluted, applied to a tonsil at the beginning of an acute attack may be beneficial as a disinfectant and counterirritant. The same preparation applied over the appendical area when slight localized pain exists, with or without notable resistance, is probably useful at the time by reason of its resolutive effect, apart from the idea that it can act deeply upon hidden parts through its other properties.

In a measure, both tonsillar disease and appendicitis are prevented by sufficient regular fecal evacuations, and while in the one case the throat remains healthier, in the other so does the appendix. Among the remedies which have been vaunted to shorten and lessen acute tonsillitis is there a drug which, taken internally, merits our confidence? I know of only one in which I still retain a fair amount of faith, in some instances, and it is guaiacum. Extolled, as we know, by many writers, and especially Sir Morell Mackenzie, it does seem occasionally to be really efficacious, not only locally, but internally.

The lozenge is, when it can be given to adults and to children half grown, the best form in which to prescribe it. In mixture, it is nauseous and upsets the stomach, as I know.

Locally, as a remedy, I place great reliance upon the use of tincture of perchloride of iron and glycerin, 1 drachm to the ounce, applied to the tonsils, pharynx, and uvula, several times in twenty-four hours. It is an astringent and local disinfectant of very great value. The sole objection to its use is the injurious effect upon the teeth and the fillings. So far as possible, all direct contact with them should be avoided. As an additional precaution the mouth should be rinsed after each application with a throat brush, always avoiding any gargling which would wash off the application from the throat and thus neutralize largely any curative effects.

In connection with the use of the iron topically and between the times of applications, I advise the use of Wadsworth's* mouth wash. This wash, diluted, two or three times with water, is notably antiseptic and astringent and is not at all harmful to the teeth. It owes its efficacy mainly to alcohol, which enters largely into its composition. There can be little doubt, also, that as a preventive measure against tonsillitis, Wadsworth's mouth wash, employed also as a gargle, is highly beneficial. I am confident that it has prevented attacks in many instances, where after exposure in crowded cars or assemblies it is thus used.

So far as the abortive effect of any remedy is concerned, when a tonsillitis is fully under way, I have my doubts. I would make an exception in favor of the use of turpentine locally applied over the affected tonsil, or tonsils, and carried sometimes to the point of blistering. Equal parts of soap liniment and spirit of turpentine, rubbed in the neck or applied on flannel, and may be, covered with thin rubber tissue, to prevent evaporation, has proved in my experience, very valuable. In one instance lately treated in the latter way, I am quite sure an abscess from a quinsy sore throat was prevented. So true is this that I do not recall another case in a stage so advanced where suppuration did not occur and in which the tonsillar enlargement and dysphagia disappeared so rapidly. Of course, one such case does not prove anything, except in so far as a comparison with other similar cases may have value. This comparison I made and I speak of the use of turpentine for that reason. True it is, the turpentine blistered the throat and to some practitioners and patients, nowadays, that might be a great objection to my advocacy. To those who have had to do with cases of quinsy sore throat and noted the great suffering from it for two or three days, or until the abscess bursts or is opened, my support of turpentine, applied locally, will come as a welcome suggestion.

Internally, the use of small repeated doses of Rochelle salt, dissolved in a little water, is to me the most satisfactory internal treatment I know of. It combats agreeably and effectively all the general symptoms and can be taken as well as any other liquid. Perhaps, given in the form of a Seidlitz powder, mixed as usual, and the carbonic acid gas allowed to escape, and then taken in tablespoonful doses every half hour or so, it is especially desirable whenever the tongue is coated, the breath foul, and there is disgust for everything—and a pill or unpalatable mixture must be carefully avoided—the first, of course, by reason of the risk and, indeed, inability of swallowing. The use of panopepton is, to my mind, the best, most available nutriment I know of given also in frequent, small repeated doses, from a teaspoonful to a tablespoonful at a time.

To children and adults, affected with follicular tonsillitis, I give freshly powdered cubebs, with the knowledge of its great curative value. One or more pinches dry on the tongue, every half hour, are evidently and rapidly effective. They very soon cause to disappear all white patches, even those which closely resemble diphtheria. To render cubebs more palatable to children, I mix with it a small proportion of sugar and sometimes add also a little nitrate of potash, if the temperature is high, or the kidneys are inactive. The combination of cubebs, powdered rock candy, and nitre was a favorite one with a late famous practitioner of Philadelphia.

Hitherto I have been considering merely the consequences and treatment of acute tonsillar infection. When the tonsils become enlarged chronically and often diseased as a result of repeated attacks of acute tonsillitis, there can be little doubt that they occasion many infections. Moreover, this tonsillar condition may be developed insidiously and without obvious preceding cause and yet the consequences to the economy in a morbid way, are unquestionable. Presumably there are a fair proportion of enlarged tonsils among children especially, and a few instances among adults, where the tonsillar hypertrophy does no special harm, at least so far as we can determine. It may be, of course, if the growth is considerable, that there is a sense of obstruction in the throat and the voice is somewhat affected, but that is about all of consequence.

When the tonsils are not only chronically enlarged, but also diseased, it is clearly our duty to

*The following is the formula of this wash: Sodium chloride (C. P.), ʒss; sodium bicarbonate (C. P.), gr. x; distilled water, ʒii; glycerin, ʒi; alcohol, ʒv; thymol and menthol, of each gr. i; oil of wintergreen, gtt. iii; oil of cinnamon, gtt. ii; oil of eucalyptus, gtt. v; tincture of cudbear, ʒiss; tincture of rhatany, ʒss. *Journal of Infectious Diseases*, Vol. III, No. 5, October, 1906, pp. 774-797.

treat them actively and effectively, so as to bring to an end much of ill health that is due to them. Many different local agents may be employed to effect this, such as iodine, nitrate of silver, the electrocautery—but finally, when the use of the foregoing has proved insufficient, proper excision by tonsillotomy or tonsillectomy remains to be done and is frequently curative, when previous means have wholly failed. Formerly, no doubt, as Dr. J. N. Mackenzie of Baltimore has shown, there were far too many tonsils removed. Of the number not a few were healthy and causing no harm. To-day, I am glad to say, the furore to operate unduly has been lessened and a saner practice prevails.

In one particular, however, I am opposed to what is now being done, *i.e.* the radical extirpation of the whole tonsil. I am confident that the excision of a portion of the tonsil is preferable in many cases. The cure of any disease in the organ itself is accomplished by this procedure and further, the functions of the throat remain later in better shape, and the general health is equally good, if not better.

In practice, the pendulum is very apt to swing too far in one way or another, and a wise conservatism is what is always most desirable because it is most useful.

The tonsil has a function that the economy needs, even though we are not agreed altogether what it is and how important it is. This statement is equally true of the appendix, which has been slaughtered so unmercifully in times past. But a new era is coming, in which both tonsil and appendix will be saved to many men and women, and later it will be fully recognized how many become sufferers in consequence of an exploitation which proceeded from narrow views of what nature provided and intended for the human body.

42 West Thirty-second Street.

WHAT PREPARATION IS THERE IN THE FUNDAMENTAL BRANCHES IN OUR DENTAL SCHOOLS FOR THE TEACHING OF ORAL SURGERY?

By A. H. LEVINGS, M.D.,

MILWAUKEE, WISCONSIN.

Oral surgery as taught today in the dental schools is a large and important subject. It includes the bacteriology of the mouth, oral sepsis, asepsis and antisepsis, dislocation of the inferior maxillary bone, fractures and tumors of both maxillary bones, surgical affections of the tongue with excision, ranula, empyema of the antrum of Highmore, ligation of the lingual, facial, and internal maxillary arteries, operations for hare-lip and cleft palate, operations on the supraorbital, infraorbital, and inferior maxillary nerves, and Meckel's ganglion, operations for salivary fistula and calculus, for ankylosis of the lower jaw, for necrosis and tuberculosis of the jaws, and should include full courses in surgical pathology and surgical bacteriology. (In addition to this one school gives a course on the eye, ear, nose, and throat, and another on rhinology.)

I submit that the dentist to understand oral surgery as taught and to practise it intelligently must be well versed in the fundamental branches upon which as a foundation his diagnosis and treatment must rest. These fundamental branches are anatomy, including embryology and histology, physiology, pathology, bacteriology, and chemistry.

In order to determine, if possible, the importance placed upon these fundamental branches in the dental schools and the time the student devotes to each, I wrote to the dental colleges in the United States asking for catalogues, and what follows is largely the result of a careful reading of these catalogues and a computation of the hours devoted to the fundamental branches in each of the dental schools. There probably are some errors in computing the hours, but in the main, I think they are correct. I received twenty-four catalogues in all.

The Indiana School of Dentistry gives nothing definite in its catalogue as to the number of hours devoted to the fundamental branches.

The Southern Dental College says that anatomy is taught in a thorough and practical manner; that the course in physiology is plain, concise, and easily comprehended. Embryology is not taught.

The Western Dental School gives nothing definite as to the course; embryology is not taught.

University of Maryland: Nothing definite in anatomy; no embryology. Pathology and bacteriology get 84 hours.

Baltimore College of Dentistry: General information only.

Louisville College of Dentistry: Nothing definite as to hours.

New York College of Dentistry: Only general information.

Washington University: No laboratory work in pathology. In the freshman year the fundamental branches get 630 hours; dental branches 540 hours. In the junior year 180 hours are devoted to the fundamental branches and 760 to the dental. In the senior year the fundamental get 120 hours, and the dental subjects the remaining.

North Pacific College of Dentistry and Pharmacology: Nothing definite.

In this connection I wish to state that in my opinion every dental school should be compelled to publish in its catalogue the number of hours devoted to each subject taught and there should be some one with authority to see that these requirements are carried out. There are quite a number of schools, however, that do give definite information as to the number of hours devoted to the fundamental sciences.

The Lincoln Dental College associated with the University of Nebraska gives the following: Operative dentistry and technique, 764 hours; pathology, dental and general, 96 hours; surgery, oral and general with anesthetics, 124 hours; oral hygiene, 32 hours; histology, general and dental, 144 hours; radiography, 60 hours; materia medica, pharmacology, and therapeutics, 96 hours; chemistry, 368 hours; dental anatomy, 256 hours; general anatomy, 256 hours; physiology, 256 hours; bacteriology, 128 hours; infirmary practice covering all branches, 1,132 hours, making in all, 4,608 hours, of which approximately 1,152 hours or less than one-fourth of the time are devoted to the fundamental branches.

In the Harvard Dental School, excepting four hours each day for four months devoted to prosthetic dentistry, the entire first year is devoted to anatomy, physiology, histology, embryology, and chemistry. In the junior year, excepting some lectures on materia medica and bacteriology and a laboratory course, the entire year is given up to dental subjects; dental pathology is taught, but no general pathology; four lectures are given on neurology.

Northwestern University Dental School: In the freshman year, 644 hours are devoted to dental subjects and in the junior year, 544. Aside from this they require 100 points in gold filling and 100 points in silver filling. Also 100 points in crown and bridge work, and 100 points in plate work. Four lectures are given on embryology. In the fundamental branches they devote 1,217 hours or about one year's work.

Colorado College of Dentistry: Nothing definite is given in regard to anatomy. Physiology gets 90 hours, histology 90, pathology 60, and chemistry 150. Embryology is not taught.

University of Buffalo: The freshmen get 300 hours in the funtamental branches, the juniors 150, and the seniors 200, making 650 hours, plus the hours devoted to dissection. This would be a little more than one-half of one year's work devoted to the fundamental sciences.

Chicago College of Dentistry: Anatomy gets 90 hours plus dissection; no embryology; no laboratory pathology, yet its students are taught to tie the facial, lingual, and internal maxillary arteries, to operate for hare-lip and cleft palate, to operate on the supraorbital and infraorbital nerves, and Meckel's ganglion, to adjust fractures and reduce dislocations, to operate for salivary fistulæ, necrosis, tuberculosis, and tumors of the maxillary bones, and ankylosis of the lower jaw.

In the University of California College of Dentistry the freshmen get 645 hours in the fundamental branches, and in dentistry 630 hours. The juniors get 390 hours in the fundamental branches and 695 hours of purely dental work. No embryology is taught and little laboratory work done.

University of Illinois: Freshmen get operative technique four half-days per week; prosthetic technique three half-days per week; dental histology, ten lectures; dental anatomy, fifteen lectures. The juniors get in pathology, one lecture a week; no laboratory work in course; prosthetic dentistry, one lecture a week; prosthetic dental laboratory work, two half-days per week and infirmary practice; orthodontia, one lecture per week; orthodontia technique, one-half day per week; operative dentistry, two lectures per week, also operative dentistry and infirmary practice; in the fundamentals they get 1,298 hours.

Ohio College of Dentistry: The freshman year curriculum includes lectures in anatomy, histology, chemistry, dental anatomy, and prosthetic dentistry, courses in extracting teeth and operative technique; also a prosthetic laboratory course, prosthetic clinical practice, and a course in dissections. The junior year includes lectures on anatomy, physiology, operative dentistry, prosthetic dentistry, chemistry, dental materia medica, dental histology, and embryology, chemical laboratory course, daily general infirmary practice, crown and bridge work, orthodontia technique, bacteriology, and anesthetics.

University of Tennessee College of Dentistry: First year students get general anatomy, histology, physiology, and chemistry, in the latter 256 hours, also dental anatomy, operative technique, and prosthetic technique. Second year students: Technique of operative dentistry, technique of prosthetic dentistry, including crown and bridge work, technique of orthodontia, materia medica, bacteriology, pathology, anatomy, oral hygiene, prophylaxis, and metallurgy; no embryology. The only subject in which they give the hours is chemistry. In contrast to this if we turn over a few pages of the catalogue we find outlined the courses in the school of medicine, and here, anatomy gets 680 hours, chemistry 656, bacteriology and histology 288 hours, physiology 376, pathology 272, and embryology 80. In the fundamental sciences in the first year the student gets 1,126 hours; in the second year 1,120 hours.

University of Minnesota Dental School: They divide their course into 171 credits. Out of these the fundamental branches get 62, and the dental branches 109; that is, about one year's work is done in the fundamental branches.

Marquette University School of Dentistry: The freshmen get 656 hours in the fundamental branches, and in dentistry 480 hours, making 1,136 hours in all. The juniors get 512 hours in the fundamental branches and 608 in the dental branches, making 1,120 hours in the junior year devoted to didactic and purely dental work. This does not include laboratory work in histology, prosthetic dentistry, pathology, bacteriology, orthodontia, physiology, materia medica, toxicology, and crown and bridge work. That is, 1,136 hours in the freshman year and 1,120 hours in the junior year are devoted to didactic work, dissections, and laboratory chemistry. As these hours are about the full quota generally required of a student, practically no time is left for laboratory work in the other branches.

No one can read these catalogues without gaining the impression that the dental schools consider the fundamental branches of secondary importance and give the greatest prominence, that is, two-thirds of their time to purely dental subjects, such as dental anatomy, operative technique, dental technique, prosthetic dentistry and technique, and orthodontia. In other words, the most advanced of the dental schools in this country at the present time are devoting only about one year to the fundamental branches while some of the schools apparently do not give more than six months to these branches. It may be contended that this is right and proper; at least, by this course, the American dentist has become renowned as a technician the world over; but while this teaching makes artists of dentists it may be questioned if it makes scientific men of them. Nor is the present course in the fundamental branches a proper foundation in any way upon which to build a superstructure for oral surgery, which requires a thorough knowledge of the fundamental branches.

The students of dentistry whom I have taught cared little or nothing for any subject not directly related to the oral cavity, nor could I enthuse them with any subject not intimately related to dentistry. Instead of taking a full course in anatomy, they wanted a short special course; instead of a thorough knowledge of chemistry, they wanted only a smattering, instead of a thorough understanding of pathology they wanted only dental pathology, and the same in physiology and histology.

This, I believe, is the fault of the dental faculties or of the dentists, for these students enter the dental college with the idea that only a smattering of the fundamental sciences is necessary. A student entering a medical college with the idea of becoming a specialist in ophthalmology, otology, rhinology, or dermatology does not ask or expect or contemplate limiting his studies to the subjects which relate specifically and only to the organ or structures to which he expects in the future to devote his attention; but he enters the class with other students in order to obtain a thorough knowl-

edge of the fundamental branches, which knowledge he will find absolutely essential to his future success. These are but specialties of medicine, and dentistry should be a specialty of medicine. As the course in the dental colleges is now outlined and taught, it is my opinion that oral surgery should be expunged from the curriculum.

I am informed that a great many, perhaps the majority, of the dental schools in this country are private institutions. I cannot but feel that this is a stumbling block, if not *the* stumbling block, in the way of proper progress. So long as the number of students in a dental school and student's fees are dominating factors, there is little hope of betterment in dental education.

During the last twenty-five years dentistry has stood still in so far as any improvement in the teaching of the fundamental branches is concerned or special increase in the length of course. During the same time the course in medicine has been increased from three to six years. Dentistry has an honorable past; dentistry has been and is of the greatest benefit to mankind, but if the dentistry of the future is to keep pace with medicine and be something more than a training in technique, something broadly scientific in addition to handicraft, then the schools of dentistry will be obliged to make marked changes in their curriculum.

These changes should contemplate two full years of work in the fundamental branches and in addition, a course in surgical pathology and surgical bacteriology and a lengthening of the course of study by at least one year.

The student who is going to do only dentistry requires this training, while it is absolutely essential for the man who contemplates practising oral surgery.

609 Wells Building.

FOOT TROUBLES AS A FACTOR AFFECTING HUMAN EFFICIENCY.

By J. B. TYRRELL, M.D.,

CHICAGO, ILL.

Education, as the term applies in government circles, has a direct bearing on all questions affecting reform in any line of endeavor. If, for example, the United States Government had placed several thousand workmen in the Isthmian canal zone, without the formality of first inculcating into their minds the supreme importance of sanitary measures, the result would no doubt have been failure, as was the case with the French who had failed in more than one attempt. Human efficiency, likewise, can be attained only by education of the public in matters pertaining to individual comfort and bodily health. It has been estimated that each and every human being represents in money value to the Government or State, $2,900. Increase in efficiency of live stock and conservation of natural resources means an increased value to the State in actual dollars and cents. Increase in human efficiency means conservation of health and producing power in the individual, and consequently an increased money value to the State.

How the foot is a factor in human efficiency can be readily understood by anyone who has ever given the subject any thought. Within the experience of all of us, the sidewalk has changed from a soft to a hard one. In a soft walk the foot shapes the ground, but on any unyielding one the sidewalk shapes the foot. Therefore, the type of foot of the savage can no longer be considered as a type of foot that will sustain us without pain and discomfort under modern conditions. The Indian or the Japanese will go to pieces on our sidewalks and contract weak feet; or, if he had such before, they will suddenly become more painful. The front part of the foot with its small muscles, mainly for maintaining equilibrium, is put out of commission by use on a surface upon which it cannot make an impression. This means a loss of function of these muscles and ligaments and a consequent weakness. It is, as we shall learn, after all a question of function, and not one of structural change entirely. I do not maintain that this is the only etiological factor, but it is one that goes far in explaining the great increase in this condition. Before studying the end results of flat or weak feet we must first consider the normal foot and its shape. In a normal foot there are four distinct arches, two being all that it is necessary to consider at present; these are the internal longitudinal, running from the os calcis forward to the phalangeal bones, the highest point of which is at the astragalo scaphoid articulation; and the anterior or metatarsal arch, which runs across the foot from the first to the fifth metatarsophalangeal articulation, the highest point being at the second of that group. These act as springs, supplying the elasticity of the foot; therefore a weakness or depression of the arches, with loss of natural elasticity, gradually forces a foot into a deformed position as a result of the superincumbent weight of the body and use of improper shoes.

As depression of the longitudinal arch occurs, the foot elongates on the inside causing abduction of the fore foot, which eventually assumes a position of valgus: the os calcis rotates inward and downward carrying the astragalus with it. This descent and rotation produce a separation of the articular surfaces of the astragaloscaphoid, astragalocuneiform, and astragalotibial articulations; naturally this means a stretching of all these ligaments, and will eventually produce extreme tenderness and marked pains through the foot, with spasmodic contractions in several groups of muscles not only of the foot but of the leg as well.

Still another set of discomforts results from a depression of the anterior arch. Elevation of the heels (high heel shoe) throws more weight on the distal extremities of the metatarsal bones; further weight resulting from the weak longitudinal arch imposes more force, and a chronic depression finally results, producing pains and cramps which Morton described nearly 40 years ago. This is Morton's neuralgia, or metatarsalgia. This pain pierces the foot radiating from the point of greatest depression, usually at the fourth metatarsophalangeal articulation. The pain is extreme and excruciating and pressure is unendurable. Cramps through the calf muscles, especially at night, are frequent in these cases.

So much for the actual mechanism. What occurs as a result? The whole postural attitude of the victim changes. The patient involuntarily abducts the whole foot far beyond the normal weight bearing angle until the whole leg is rotated outward, causing a tension and subsequent stretching of the capsule and ligaments of the inner side of the knee joint, a rotation outward of the tibia upon the femur; therefore pain through the inside of the knee radiating upward from the head of the tibia, sometimes through the outside of the knee

with a sense of tightness back of the knee, results; and this the patient tries to overcome and relieve by bending the knee and assuming a position of genu valgum. Since rotation of the leg has occurred, hip-joint changes follow. The femoral head is rotated forward, throwing the line of weight anteriorly in the acetabulum, at once producing a laxity of the posterior capsule and iliofemoral ligaments, the anterior ones being at the same time tense and stretched.

Purely from fatigue in supporting the body in this badly balanced posture, the patient will in time allow the pelvis to sag or tilt backward until its upper plane, instead of lying in an angle of 30°, will be nearly horizontal. The tilting of the pelvis carries the sacrum backward and downward, with it the whole lumbar spine, causing a flattening or obliteration of the normal lordosis in that region, and thrusting the entire trunk out of balance. Furthermore, to compensate this new alignment, the dorsal spine and shoulders are bent forward, and the sternum and chest wall are depressed. The whole body balance is lost and to overcome it postural deformity must ensue.

Let us consider for just one moment what occurs to the spine in the lumbar and lumbosacral regions, as these are the points most affected. Obliteration of the normal lordosis would actually compress the anterior portion of the vertebral bodies, pinch or mash the intervertebral discs, and cause abnormal tension and stretching of the muscles and ligaments and fibrous bands of the posterior portion, as well as an actual separation of the vertebral bodies.

The axes of both pelvis and abdominal cavities are changed. All these physical changes in the spine are bound to produce pain. That is just what occurs. Pain develops in the lumbar region, induced by undue pressure from weight to the anterior portion of the vertebral bodies and to the tension and stretching of ligaments posteriorly, with the posterior separation adding to it. These pains become chronic, and may radiate forward and down the thighs, simulating sciatica. We hear the old familiar complaint of weakness in the back and, in cases of long standing, pain which is relieved only in the prone position; again the old familiar "stiffness" upon rising till the patient limbers up. After standing for a while the old annoyance will return as before.

What effect will all this postural change have upon the abdominal and thoracic viscera? When the forward curve of the lumbar region is lessened or obliterated a great many of the normal supports or shelves are lessened and more weight is necessarily thrown upon their respective mesenteric and peritoneal attachments. These, in time, give way to a constant tension and strain, visceroptosis results, with chronic constipation as a secondary evil. With the increase in the habitual or postural deformity, the anteriorposterior diameter of the thorax is decreased. This deformity restricts thoracic and increases abdominal breathing, thereby increasing intra-abdominal pressure, and affecting especially the anchorage of the liver and stomach, and interfering physically with their functions.

When a patient presents as the most prominent symptoms, chronic backache, chronic constipation, nervous irritability, and sometimes digestive disturbances, he may not complain of foot trouble at all, and the physician on first thought would look for some trouble in the lumbar section or possibility in the sacroiliac synchondroses. But careful examination in this region will reveal no disturbance, until possibly he will find a tightness back of the knee. Then an examination will disclose markedly pronated feet, depressed plantar arch with often a complication of anterior arch weakness. It is not because of the foot troubles probably, that they consult a physician, and, conversely, not all patients with static foot trouble have the more serious complications, because, in all probability, they seek relief before complications develop.

The significance of this affection, not only as a source of local pain, but as a predisposing and aggravating cause of disability of neighboring joints and of profound disturbances in other organs of the body, is now more generally recognized by the profession, and the use of the more popular terms fallen or falling arches, instead of flat foot, gives a better understanding of its nature—an acquired weakness that may be prevented or cured.

As evidence of a thorough study of the condition by the profession the records that appear in the Reports of the Hospital for Ruptured and Crippled in New York are convincing. In 1890, in the orthopedic department arch trouble embraced 2.6 per cent. of the new patients treated. In 1906 the percentage had risen to 18.3, and in the last report to 29.2 per cent.

The paramount question is: What are you going to do for this condition? It is with us, what are we to do to correct or counteract these tendencies? The weak foot is, in most instances, an acquired disability which under favorable conditions may be cured, and this, rather than the relief of symptoms, should be the aim of treatment.

The weakness is due to deformity and the impaired function that accompanies it. The first indication therefore is the restraint of deformity, since symmetry, in other words, the normal relationship of the joints, is essential to normal function. Effective treatment should prevent not only actual deformity, but, on the principle of natural resiliency, should stimulate muscles and ligaments, weakness and atrophy of which predispose to it, as well. Logically, then, supports are necessary. The B. & B. adjustable arch support meets these indications. It is not a steel brace, but a double spring metal arch with a leather sole superimposed. It is resilient, combining this feature with great strength, and it is light and adjustable, either to model or to the natural foot. It is not meant to supplant other well-known methods of treating weak feet, but is a necessary supplement to massage, exercises, and the use of proper shoes, etc. This form of support serves the same purpose as the celluloid support offered and used by Lange of Munich, and in this country by Geist and others.

1449 North LaSalle Street.

Case of Possible Insufficiency of Endocrinic Glands.—F. G. Crookshank reports the case of an apathetic and flaccid male infant aged 32 months who did not speak and seemed to have extremely little initiative. Some of the features were suggestive of mongolism; there was a marked Hapsburg lip. The vault of the nasopharynx was very small and the respiratory system generally poorly developed. The upper part of the trunk and the arms were relatively less developed than the belly, which was protuberant, and the legs, which were large and shapeless. There was a marked dimple above the anus. For some weeks the patient was given thyroid and thymus tablets and improved. It was thought that the child had in addition to some degree of mongolism, some pituitary as well as genital insufficiency.—*Proceedings of the Royal Society of Medicine.*

MEDICAL RECORD.

BLOOD PRESSURE AND PULSE PRESSURE IN ARTERIOSCLEROSIS AND NEPHRITIS.

THE generally prevailing belief that all cases of arteriosclerosis and of nephritis are accompanied by high blood pressure must be corrected in the light of recent investigations. The importance of blood pressure studies from the viewpoint of diagnosis and prognosis in both of the above conditions cannot be exaggerated, but an essential element in gauging the limitations of these studies is the recognition of the fact that in a fairly large percentage of cases of arteriosclerosis and nephritis the blood pressure is normal or may be even subnormal. These facts have been pointed out by a number of observers during the past few years. They are brought into particularly sharp relief by the recent observations of W. Janowski in the *Zeitschrift für klinische Medizin*, Vol. 80 Nos. 5 and 6.

The material upon which these observations are made comprised 350 patients. They are classified into three groups as follows: (1) There were 200 cases of arteriosclerosis in which urinary examination excluded nephritis. (2) There were 50 cases of arteriosclerosis with a coincident primary or secondary nephritis. (3) There were 100 cases of nephritis of various types which were not complicated with arteriosclerosis. Regarding the normal blood pressure as varying between the limits of 80 and 120 mm. Hg, and the normal pulse pressure as varying between the limits 22 and 40 mm. Hg, the author found that of his 200 cases of arteriosclerosis there was an increased blood pressure in 72 per cent. It is concluded that an increased blood pressure must be regarded as a valuable symptom of arteriosclerosis. The exceptions, comprising nearly one-third of the cases, in which the blood pressure is normal or subnormal, may be said to "prove the rule," for these exceptions can be explained on the basis of certain well-marked clinical factors. Among 55 arteriosclerotic patients with a normal blood pressure there were 52 in which there was evidence of an impairment of the functional power of the heart, which impairment prevented the blood pressure from reaching the height characteristic of arteriosclerosis. In 16 of these patients stenocardiac attacks were common. It is pointed out that angina pectoris occurs more frequently in arteriosclerosis with normal blood pressure than in arteriosclerosis in which the blood pressure is heightened. The above facts are of eminent significance, indicating that one must regard as particularly serious all cases of arteriosclerosis in which the blood pressure is normal or subnormal. In these cases there is a pronounced impairment of the nutrition of the heart muscle, manifesting itself in a disturbance of conductivity, as a result of which the heightened blood pressure cannot be maintained in the distal parts of the arterial tree.

The second group, comprising 50 cases in which arteriosclerosis was coincident with a nephritis apparently secondary to sclerosis of the smallest renal vessels, showed a considerably higher rise in blood pressure than cases of arteriosclerosis not complicated by nephritis. Only in 8 per cent. of the cases of the latter category was there a blood pressure greater than 180 mm. Hg, while of the former category this limit was exceeded in 58 per cent. of the cases. Moreover, in arteriosclerosis complicated with nephritis there is a considerable rise in the pulse pressure. These observations agree with those made by other authors.

The third group, including the 100 cases of nephritis in which arteriosclerosis was not evident, are again subdivided into the cases of acute and those of chronic nephritis. In the 7 cases of acute nephritis the blood pressure varied between 130 to 180 mm. Hg, and was the highest when the symptoms were most pronounced, and particularly during the development of uremic manifestations. Both pulse pressure and blood pressure show this rise coincident with the onset of uremia, a fact not only of diagnostic but also of prognostic significance. Systematic blood pressure estimations in acute nephritis enable one to follow the course of the disease most accurately, and consequently to predict a happy outcome when the blood pressure sinks to normal.

The cases of chronic nephritis present facts of striking interest. They comprise two groups, in one of which the blood pressure is normal, and in the other of which (including 84 per cent. of the cases) it is heightened. This observation, together with the results of the various functional tests, indicates that the older classification of the parenchymatous, the interstitial, and the mixed types of nephritis is no longer in accord with clinical facts. Janowski inclines to the classification of the French school under the leadership of Widal, which recognizes four types of nephritis, as follows: (1) This group includes patients with so-called urinary symptoms, such as the presence of variable amounts of albumin, casts, and blood cells in the urine. These patients for a number of years manifest no other signs of renal disease, and these signs arise only toward the terminal stage of the nephritis. (2) This group presents the symptom-complex of chloride retention, with various degrees of edema, vomiting, diarrhea, obstinate headache, convulsions, coma, Cheyne-Stockes breathing, cerebral irritation, and amblyopia. (3) In this group the symptoms of nitrogen retention occupy the foreground. In the pure cases of this type there is no edema, but there are pronounced anorexia, pruri-

tus, vomiting, stomatitis, and stupor which often deepens into coma. Retinitis and pericarditis may complicate this picture. (4) The last group is characterized by the high blood pressure which prevails from the very outset of the disease. The patients suffer from obstinate headache and vertigo, tinnitus, disturbances of vision, muscular twitchings, and numbness in a finger or in an entire hand. The blood pressure is very high. The heart is enlarged and gallop rhythm is frequently observed. In time symptoms of chloride or of nitrogen retention or of cardiac insufficiency develop. But apart from these the greatly increased blood pressure may give rise to such complications as hematuria, epistaxis, retinal hemorrhages, cerebral hemorrhage, and acute edema.

VACCINES IN PERTUSSIS.

SINCE the positive demonstration of the pathogenicity of the Bordet-Gengou bacillus in pertussis, many papers have appeared reporting the use of vaccines of this organism in the treatment of the disease. These reports have, as a rule, been of a rather optimistic nature, though generally summarizing a comparatively small number of cases. The use of the vaccine as a prophylactic measure has been much less extensive and, so far as the literature affords information, no adequate opportunity has been had to test its efficacy.

Recently Alfred Hess has reported ("International Clinics," 1914, vol. iii, Series 24, p. 97) his observations on the use of pertussis vaccine in both prophylaxis and treatment in an epidemic of whooping-cough in an orphan asylum housing about 350 children. He used four different vaccines. Two were commercial preparations, the third was made from a laboratory strain of the organism, while the fourth was made from strains isolated from cases in the asylum. Two hundred and forty-four children received preventive inoculations, of whom twenty-one later developed the disease. Of these one-half received the commercial vaccines. The other preparations were apparently more protective in their effect, although of the 199 who received them, nine afterward exhibited symptoms of whooping-cough. One hundred and thirty children received no protective inoculation. Of these thirty were infants confined in a ward by themselves. No cases developed in this ward and they were therefore not exposed. Twenty-five were in another ward in which one patient had the disease. These were also infants and confined to bed so that the exposure was not at all intimate and there were no secondary cases, a fact which "shows the difficulties in judging of the results of prophylactic treatment." Among the other seventy-five children sixty had whooping-cough.

It would seem, therefore, from these figures that the vaccine had a distinct prophylactic value even though its action was not always sure, and even though the percentage of severe cases was just as high in the inoculated as in the uninoculated. There was no evident excuse for the failure of its action at times so that it seemed necessary to conclude that sometimes "it doesn't work." The epidemic was a comparatively mild one, there being no fatalities and but two cases of pneumonia, but the author failed to see that the administration of vaccine had any discoverable beneficial effect on the course of the disease. He does note, however, that "in no instance did any harmful local or systemic reaction follow the injection of the vaccine."

The pertussis vaccine, therefore, shows a certain amount of analogy to the typhoid vaccine in the manner of its action, in that it seems to be more powerful as a preventive than as a curative agent. Its use is especially recommended in institutions to prevent the spread of the disease. It is interesting to read that all attempts to use the vaccine for diagnostic purposes, whether by the cutaneous, intracutaneous or subcutaneous methods, proved failures.

THYMUS DEFICIENCY SYMPTOMS.

THE picture caused by thymus deficiency is variable, or else involved in technical errors of experiment and observation. According to some investigators removal of the organ in young animals leads to osseous changes while others find the bones intact. Some discrepancies are due, doubtless, to the fact that certain finds are merely transitory. Failure to extirpate the entire gland is perhaps also responsible for negative results. Some experiment animals are said to have been inbred to the point of degeneracy. In certain experiments there was suppuration of the operation wound. Experiments which have been most free from objection appear to show that thymus deficiency symptoms are as good as nonexistent in the present state of our knowledge. Thus far we know nothing of compensatory activities in other organs. A plus state of the thymus appears to play a role, not mechanical either, in the genesis of thymic asthma and of some cases of Graves' disease. At a recent session of the Berlin Surgical Society (*Deutsche medizinische Wochenschrift*, August 27) Nordmann, whose views are expressed in the foregoing lines, asserted that as yet we have neither a physiology nor a pathology of the thymus gland, and that our clinical knowledge of the course of its diseases is equally defective.

PRESENCE OF TETANUS GERMS IN FELT.

THAT substances useful in medicine and surgery may contain the germs of lockjaw is well known. We may mention commercial gelatin and charcoal in this connection. Quite recently Kirmisson has found that felt so commonly used in orthopedic retentive dressings may contain tetanus germs in abundance (*Berliner klinische Wochenschrift*, August 17). Two patients who had been treated with Abbot's scoliosis method lost their lives as a result of infection from the felt plates used to make a retention support. One case was so fulminating that death occurred in twenty-four hours after trismus began. The other case was also acute. It is the custom at a particular stage of treatment to insert the felt plates between the gibbosity of the spine and the dressing proper. In this manner small ulcers were produced and promptly infected. Cultures of tetanus bacilli were grown in abundance from the felt.

MOTION PICTURES OF OBSTETRICAL OPERATIONS.

IT was long ago evident that the cinematograph could be made to do much for the small, remotely situated medical college in the direction of replacing in clinical instruction actual demonstrations on the living. The pictures would necessarily come from the large medical centers, inferentially in the case of obstetrics from the large lying-in hospitals. Manipulations could be shown on the scale of magnitude and at the rate of speed best suited for the occasion. At a meeting last summer of the Freiburg Medical Society Gauss (*Berliner klinische Wochenschrift*, September 7) exhibited films of this sort and demonstrated that they possessed great didactic value and rendered as good service within certain limits as could be desired.

News of the Week.

Army Medical Corps Examinations.—The Surgeon General of the Army announces that preliminary examinations for appointment of First Lieutenants in the Army Medical Corps will be held on January 11, 1915, at points to be hereafter designated. Full information concerning these examinations can be procured upon application to the "Surgeon General, U. S. Army, Washington, D. C." The essential requirements to secure an invitation are that the applicant shall be a citizen of the United States, shall be between 22 and 30 years of age, a graduate of a medical school legally authorized to confer the degree of Doctor of Medicine, shall be of good moral character and habits, and shall have had at least one year's hospital training as an interne, after graduation. The examinations will be held simultaneously throughout the country at points where boards can be convened. Due consideration will be given to localities from which applications are received, in order to lessen the traveling expenses of applicants as much as possible. In order to perfect all necessary arrangements for the examinations, applications must be completed and in possession of the Adjutant General at least three weeks before the date of examination. Early attention is therefore enjoined upon all intending applicants. There are at present twenty vacancies in the Medical Corps of the Army.

A Women's Medical Club.—At a meeting of twenty-five women physicians, held October 18 at the residence of Dr. Hannah M. Graham in Indianapolis, an association to be known as the Indianapolis Women Physicians' Club was organized. The ultimate aim of the organization is to establish a children's hospital, and it will also be ready to advise with any of the public officials on matters relating to the health of women and children. The president of the new society is Dr. Hannah M. Graham and the secretary, Dr. Lillian B. Mueller.

Health in the Philippines.—According to the report of the Bureau of Health for the Philippine Islands for the first quarter of the present year, the health conditions in the archipelago were then very much better than they had been any time during the past ten years. The death rate of Manila for March was 20.39 per 1,000, which is the lowest on record, and when compared with the rate of 40.23 per 1,000 for March, 1904, an idea of the health transformation may be gained.

Revision of the Sanitary Code.—A general revision of the New York City sanitary code has been undertaken, with the purpose of bringing the code into conformity with the great body of municipal ordinances recently remodeled by the Codification Committee of the Board of Aldermen.

Gifts to the Georgia Medical Society.—Dr. Isaac Minis Hays of Philadelphia has presented a gift of 450 bound volumes to the Library of the Georgia Medical Society, located in the new Hall of the Society at Savannah, Ga. Dr. W. W. Owens of Savannah has presented to the Library an engrossed and framed copy of a quaint old notice of meeting issued by the Society in 1807.

No Preservatives in Antimeningitis Serum.—The statement having been made that certain untoward symptoms following the spinal administration of antimeningitis serum were due to the action of trikresol used as a preservative, the New York City Health Department has decided not to add any preservative to the serum prepared in its laboratory. This has been done, despite the fact that the Department has never observed a single instance of collapse in the hundreds of cases in which its physicians have administered the serum, in order that neither physicians nor their patients may hesitate to use the serum freely in cases of cerebrospinal meningitis.

Alvarenga Prize of the College of Physicians of Philadelphia.—The College of Physicians of Philadelphia announces that the next award of the Alvarenga Prize, being the income for one year of the bequest of the late Señor Alvarenga, and amounting to about $250, will be made on July 14, 1915, provided that an essay deemed by the Committee of Award to be worthy of the prize shall have been offered. Essays intended for competition may be upon any subject in medicine, but cannot have been published. They must be typewritten, and if written in a language other than English should be accompanied by an English translation, and must be received by the Secretary of the College, Dr. Francis R. Packard, 19 South 22d street, Philadelphia, on or before May 1, 1915. Each essay must be sent without signature, but must be plainly marked with a motto and be accompanied by a sealed envelope having on its outside the motto of the paper and within the name and address of the author. It is a condition of competition that the successful essay or a copy of it shall remain in possession of the College; other essays will be returned upon application within three months after the award. The Alvarenga Prize for 1914 has been awarded to Dr. H. B. Sheffield, New York City, for his essay entitled: "The Fundamental Principles Involved in the Use of the Bone Graft in Surgery."

Personal.—At the annual meeting of the West Side German Dispensary and Hospital, New York, held October 29, 1914, Dr. Homer Gibney was appointed to succeed Dr. John L. Adams (recently deceased) as president of the Medical Board; Dr. Max J. Schwerd as vice-president, and Dr. E. L. Kellogg, secretary.

Dr. Theodore C. Janeway has removed from New York City to the Johns Hopkins Hospital, Baltimore.

Dr. William Seaman Bainbridge, of this city, delivered a lecture on October 27 before the medical students of the National University of Arts and Sciences, St. Louis, on "The Surgical Treatment of Chronic Intestinal Stasis." On this occasion Dr. A. R. Kieffer, president of National University, con-

ferred the degree of Master of Surgery (C. M.) upon Dr. Bainbridge.

Harvey Society.—The third lecture of the present course will be delivered at the Academy of Medicine by Prof. A. S. Loevenhart of the University of Wisconsin on Saturday, November 7, at 8.30 P.M. The title of the lecture is "Certain Aspects of Vital Oxidation."

A Course of Lectures for Employees of the New York City Department of Health.—The work of the Department of Health is so varied and progress in public health work in recent years has been so rapid, that it is difficult for the various inspectors and nurses employed in the Department of Health to keep informed concerning the activities of the different bureaus. Yet in order to render efficient service both to the Department and to the public at large, it is highly important that they not only possess such information, but in addition be familiar with progress in medical and sanitary science. With this in view, the Bureau of Public Health Education has organized a series of lectures constituting, as it were, a school of sanitary science for Health Department employees. The lectures are to be held weekly at 4 o'clock, from October 15 to March 3; the lectures for Medical Inspectors and Field Nurses in the Assembly Hall at Hunter College, Park avenue and 68th street, the lectures for Lay Inspectors on the fifth floor of the Department of Health building, 139 Center street, and the courses for Hospital Nurses, in their respective hospitals. Although attendance will not be compulsory, employees are expected to be prepared, when the course terminates, to pass an examination on the subjects discussed. The public is also invited to attend all the lectures except those to hospital nurses which are to be given in the Department's hospitals for contagious diseases.

New Hospitals.—The new dispensary of the Hospital for Deformities and Joint Diseases at 43 East 123d street, New York, was dedicated with appropriate ceremonies on Tuesday afternoon, November 3.

The Springfield, Mass., Free Hospital was opened for the reception of patients on October 13.

St. Luke's Hospital, Portsmouth, N. H., has recently been opened. It now accommodates twelve patients only, but will soon occupy a larger building with a capacity of twenty-five beds.

A modern hospital erected and equipped at a cost of $165,000, has been presented to Indiana county, Penn., by Adrian Iselin, Jr., and his sister, Miss Georgine Iselin of New York City.

New York City Charities Criticised.—The August Grand Jury, which has been investigating the institutions under the control of John A. Kingsbury, Commissioner of Charities, handed to Judge Nott in General Sessions yesterday a presentment severely criticising present conditions. It finds that many of the homes and hospitals are greatly overcrowded and that the food in some cases is unsatisfactory in quantity, quality, and preparation. The suggestion is made that the management of the institutions be taken out of the hands of a Commissioner and be put in the hands of a Board of Charities.

Obituary Notes.—Dr. WALTER SAMUEL BAKER of Newark, N. J., a graduate of the New York Homeopathic Medical College and Hospital in 1863, died at his home suddenly, from cerebral hemorrhage, on October 26, aged 73 years.

Dr. ISAAC G. WORRALL of Cresskill, N. J., a graduate of the New York University Medical College in 1850, died recently at his home, aged 86 years.

Dr. FRANCIS LESTER BABCOCK of Dedham, Mass., a graduate of the Boston University School of Medicine in 1879, a member of the Massachusetts Homeopathic Medical Society and the American Institute of Homeopathy, a former member of the Board of Health of Dedham, and for many years physician to the Dedham House of Correction, died at his home on October 26, aged 65 years.

Dr. DAVID C. HARMISON of Havana, Ill., a graduate of the College of Physicians and Surgeons, Keokuk, Ia., in 1878, and a veteran of the Civil War, died at his home on October 20, aged 70 years.

Dr. FRANK H. HOBBS of Waterboro, Me., a graduate of the Medical School of Maine, Portland, in 1900, and a member of the Maine Medical Association and the York County Medical Society, died at his home, following an operation for appendicitis, on October 11, aged 55 years.

Dr. PHILLIP E. PARKER of Bay City, Tex., a graduate of the Tulane University of Louisiana, School of Medicine, New Orleans, in 1885, and a member of the American Medical Association, the State Medical Association of Texas, and the Matagorda County Medical Society, was accidentally shot while hunting and died from his injuries on October 16, aged 56 years.

Dr. WALTER D. GREEN died as a result of a railroad accident at Bellemead, N. J., on October 25, at the age of 53 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1886. He subsequently became resident physician in the Presbyterian Hospital and later in the Pennsylvania Hospital. In 1892 he became assistant medical inspector for the Philadelphia Bureau of Health and in 1894 he was appointed physician for the Port of Philadelphia.

Obituary.

GEORGE LIVINGSTON PEABODY, M.D., NEW YORK.

Dr. GEORGE LIVINGSTON PEABODY, who retired from practice in New York City in 1909, died suddenly from heart disease at his home in Newport, R. I., on October 30, aged 64 years. Dr. Peabody was born in New York and was educated at Columbia University, receiving the degree of A.B. in 1870 and of A.M. in 1873, in which year also he was graduated in medicine from the College of Physicians and Surgeons. After post-graduate study in Vienna, Strassburg, Paris, and London he returned to this city, and in 1878 was appointed pathologist to the New York Hospital, thus beginning a connection which lasted through a long service as attending physician from 1884 until 1909, when he became a consultant. In 1884, also, he was appointed clinical lecturer in medicine at the College of Physicians and Surgeons, and in 1887 became professor of materia medica and therapeutics, retiring in 1903. He had also served as attending physician to the Roosevelt, Bellevue, and St. Luke's Hospitals. From 1884 to 1890 he was one of the Trustees of Columbia University and from 1891 to 1895 a member of the University Council. He was a member of the Association of American Physicians, the New York Academy of Medicine, the Practitioners' Society, the Association of the Alumni of the College of Physicians and Surgeons, and the Century and University Clubs.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

MEDICAL SOCIETY OF LONDON, PRESIDENT'S ADDRESS—CANCER OF GASTROINTESTINAL TRACT—DISEASES AMONG TROOPS—WOMEN SURGEONS AT ANTWERP HOSPITAL—HOSPITAL SHIPS FOR INDIAN TROOPS—OBITUARY.

LONDON, October 16, 1914.

THE new session of the Medical Society of London was opened on Monday as I informed you would be the case. The retiring president, Sir D. Ferrier, received a unanimous vote of thanks to which he replied, and after the other retiring officers had been similarly thanked he introduced his successor, who had been previously elected, viz.: Sir John Bland-Sutton, and invested him with the badge of office. Sir John then took the chair and delivered his introductory address, which he devoted to "Cancer of the Duodenum and Small Intestine." He began by remarking on the unequal distribution of cancer in the gastrointestinal tract—common in the stomach, but between the pylorus and ileocecal valve uncommon. Primary cancer is rare in any part of the small intestine, but is more frequently seen in the duodenum, short as it is, than in the jejunum or ileum. Contrary to some he does not think duodenal cancer arises in chronic ulcer. Malignant disease of the duodenum of any kind is uncommon and there are few specimens in our museums. It may not be of practical importance to fix the precise locality of this cancer, but when it arises in the ampulla it exhibits remarkable peculiarities. Nowhere else in the body does so small a growth lead to such grave consequences. It may, when no bigger than a cherry, block the flow of bile and pancreatic juice, setting up intense jaundice and emaciation—if three clinical signs are painlessness, jaundice and emaciation. In spite of its local nature it is quickly postal—mostly within six months. The daring resourcefulness of modern surgery has attempted to deal with it, and Sir John did not doubt that success will eventually be attained. The disease is more frequent in the transverse or infra-ampullary position, and the symptoms then resemble cancer of the pylorus, but the vomit contains bile and pancreatic juice and may be very offensive. In the small intestine any kind of tumor, the president said, was rare but interesting, and the benign were generally pedunculated. The propulsive efforts provoked by them are apt to lead to intussusception. Then he mentioned accessory pancreas because some who still hold that cancer arises in embryonic vestiges think this may arise in islands of pancreatic tissue, though there is no evidence of such a thing or that duodenal cancer results from changes in Brunner's glands or that parotid chondroma arises from relics of Meckel's cartilage—theories which indicate that pathologists as well as poets have imagination.

After referring to hyperplastic tuberculous affections the president described melanosis of the colon, which has not received much attention in this country. The condition is a curiosity, but if detected in the course of a clinical examination might receive undue attention, so that further observations on this curious pigmentation would be useful.

In conclusion the president announced a discussion on the surgery of tumors of the intestine at the next meeting. It was also hoped to have an exhibition of specimens of tumors and hyperplastic tuberculous disease, and the society would be grateful for the loan of specimens, particularly any illustrating cancer of the vermiform appendix about which there is much uncertainty. Pigmentation of the colon also deserved more attention.

In such circumstances as we are passing through the precautions taken by army medical officers against the outbreak and spread of diseases among troops call for extra attention from civilian practitioners. Wherever troops are quartered there is some danger that diseases affecting them may extend to the civil population, and the local government board has reminded the medical officers of health of such districts that this is the case. Under existing conditions the introduction of smallpox is not unlikely and some unauthenticated reports of its appearance in one or two places have been circulated. Typhus and typhoid are quite as likely to appear and spread, perhaps more, but every medical officer of health will be on the lookout for them, and the more efficient their arrangements for dealing with early cases the greater will be their success in preventing extension. An increase of hospital accommodation may be needed in some districts.

The Army Medical Service has been doing a great work as testified by combatant officers, who declare they have been supplied with clockwork regularity. Correspondents declare that the organization throughout is so completely satisfactory that the French commissariat is closely studying it with a view of copying some of its methods which are contrived to meet every eventuality. Unexpected changes in the movements of troops do not interrupt their supplies if need be.

The Army Service Corps will take food up to the firing line and well-fed troops are not likely to lose their nerve. The Germans, who plan to live on the country they invade, are said to have already suffered a good deal from deficiency. The British reserves and soldiers encamped for refitting get well cooked meals of meat and vegetables, etc., just as if they were in barracks at home, and regiments on the march have "army cookers" of the newest pattern and so get hot soups or stews and are said also to take hot tea regardless of the enemy's shell. Tobacco and cigarettes are looked upon as next to food, but we hear that a great desire for sweet things has developed among the men—chocolate and jam especially. This craving was stronghly marked also in the last South African campaign.

A hospital at Antwerp was organized by Mrs. Stobart and equipped by the Women's National Service League and staff by 28 women, six of whom were qualified doctors. Dr. Florence Stoney says they proved that women surgeons were of use in war conditions, for when shells were screaming overhead and part of the roof of the hospital blown off there was no sign of fear or panic, but all went about their work as orderly as if it were a picnic in the park. She made light of 18 hours under shell fire, as not one of the patients were hurt, though the nerves of some of them were shattered.

By advice of Lt. Col. W. A. Sykes, I. M. S., six vessels are being fitted up as hospital ships for the Indian troops in the present war and some of the Indian princes propose to present others. Each will accommodate about 350 patients, of which 100 will be in swinging cots (for the most serious cases) and the others in fixed iron bunks. Each ship is a complete hospital. One has already left the docks

in charge of Lt. Col. Ginslittle, late I. M. S., and another is just reaedy to start under Lt. Col. Pratt, I. M. S.

Returning to the danger of epidemics among troops, it seems already to have become realized on the German side, for this morning we have news of numerous cases of typhoid, dysentery, and pneumonia having occurred. Professor Besserer of Münster, having been sent to investigate and take measures against the outbreak, has made an unfavorable report and declared nothing else could be expected under the circumstances. It appears that soldiers had had to stay for five days and nights without a break in trenches that were flooded and in places half full of water, and still worse, during all that time no fresh provisions had reached them, with the natural result that what remained in their knapsacks became mouldy. Moreover, there was no possibility of moving the dead or wounded and though some improvement had followed a favorable change in the weather the professor naively remarks that he could give no guarantee for the future. As winter approaches and the rainy season no doubt trenches will become quite untenable and the conditions of the campaign changed.

Dr. Fletcher Little, who died recently, was a prominent advocate of post-graduate instruction and esteemed both within and without the profession for his enthusiasm in various public positions. He was a magistrate, a Cambridge M. B., 1888, M. R. C. P. Lond., 1889, and among appointments he held the physiciancy to the Temperance Hospital and that of the N. L. Consumption Hospital. He was M. O. H. for Harrow, and although a long illness, eventually fatal, had made some progress, he was able to complete his Annual Report for 1913. He visited America to study the physical methods there in vogue just previously to Weir Mitchell's work. He also took great interest in politics and contested Oxford city in 1895. He was for some years on the London County Council.

Dr. Hooper May, consulting surgeon to the Prince of Wales's General Hospital, formerly called the Tottenham Hospital, died Sept. 23, aged 83. He took the F. R. C. S. in 1858 and M. D. S. I. in 1860. He retained his mental activity, his hearing, and eyesight to the close of his life. After his first qualification he went to Edinburgh for an extra year's study under Syme and Lister. On his return he introduced the carbolic spray at Tottenham Hospital, the first in London to try it.

Mr. John Hartley, who died recently, was surgeon to the Darlington Hospital. He qualified in 1879, took F. R. C. S. in 1892, having been a student at the London and at the Middlesex hospitals. He served as demonstrator of anatomy at the latter, where also he took a turn in the resident offices. He recorded a case of recovery from tetanus after administration of intra-cerebral injeections of antitoxin.

PARIS IN WAR TIME.

To the Editor of the Medical Record:

Sir:—Things have changed since I last wrote. We have now put our tails well up in the air and are even venturing to wave the tufts gently to and fro. Now that it is all over we don't mind admitting that for a few days early in September we all had an uncommonly queer sensation in our solar plexus. It certainly looked as though the enemy were going to walk right into Paris without so much as knocking at the door; and if he had been half equal to his reputation there seemed every likelihood of such a massacre of inoffensive non-combatants as history had never registered, since there was sure to be some hothead to fire on a German from a window. It is true, the American Embassy had undertaken to affix a big poster to our doors saying that that property was under the protection of the United States; but since, of course, every German would have claimed to know no English, this seemed to promise but feeble protection. A great many of our country folk hung out the Stars and Stripes from their balconies; this was not a bad idea, though it affords me now unlimited satisfaction to feel that I postponed buying a flag until the last extremity, and that my 3-fr.-50 are still jingling in my pocket. But the really sore point with me is the stock of canned goods I laid in, in provision of the general disorder liable to ensue for a week or two after a German occupation. I explained to my housekeeper that circulation in the quarter would probably be risky for a while until things settled down, and that we must have sufficient articles of food in the house to carry us through the initial period without its being necessary for any of the womenkind to move abroad. These directions were conscientiously carried out, and I am now the distressed possessor of a stock of dried milk, sardines, biscuit, ham, tongue, cereals of every conceivable variety, cheese, tea, sugar, and dog-biscuit, that would suffice to start an orphan asylum. However, if this war drags along all winter I need scarcely say that opportunities for discreetly placing these foodstuffs will not be wanting—far from it.

Von Kluck's first rush was certainly a wonderful performance from a military point of view. The heat at that time, August 23, to the beginning of September, was excessive, for Europe, and to have covered the ground he did in about ten days, from Mons to Charleroi to Chantilly with those masses of men, will certainly take a place among the great feats of war. But it really looks as though he had utterly broken down his troops in the doing of it, completely winded them, as they have never been the same men since. So that by the time they reached the line of the Marne the Allies were able to hurl them back all along their front without too much effort. And here it is only proper to say that for generals to have been able to rally troops that had been mauled as badly as the Franco-British army had, stiffen them up for a stand, and then drive the enemy back at the double for upwards of a hundred kilometers, will rank fully as high as a performance, if not higher, than the German *tour-de-force*. It is beyond question that the general advantage now lies with the Allies; the enemy is being gradually worn down and driven back. But even were that not the case, the moral advantage is overwhelmingly theirs; for the mere fact of having brought the great early onslaught to a halt, which the Germans looked on as their trump card, and to the obtaining of which they went to such a length as the violation of Belgian neutrality, is practically equivalent to beating them. The Germans can never repeat that effort; their defeat is now no more than a question of time. In fact, this collapse of the German initiative is to me inexplicable, with the information at present available; there seems to be an element in this question that we on this side do not yet know, and which the withdrawal of men to the Russian side of the con-

test does not suffice to explain. It appears that early in the war the German advance was so extraordinarily rapid that the commissariat could not maintain the pace; the troops had therefore to live on what they had with them and on what they could find. The result was a condition that very nearly approached starvation. This hunger, combined with the killing pace, and the great heat, not to speak of the disappointment in not taking Paris, which for them must have been a terrible blow, may have demoralized them mentally and physically. Another factor that may have an important bearing on this side of the question is the French 7.5 gun. All accounts agree that this weapon is a fiendish invention and that it is served by a corps of men who are past masters in their art. The fire of this weapon is more accurate than the guns of the enemy, the timing of the shells more precise, they burst just in the right place, and the shrapnel itself is a more deadly affair and *does* burst, which appears to be often not the case on the other side. This is a matter of the greatest importance, as will be shown a little farther on. The result of this has been that the German losses, with their compact formation, have been enormous.

The war has now lasted long enough to have given certain medical and surgical results that are of no little interest, though French data alone are available up to the present. The feature that has attracted most attention in this conflict is that it is a *gunner's* war, as distinguished from a rifle contest; cannon claim most of the honors of the day, the 7.5 on the French side, and the huge siege-mortar of the Germans that is such a serious affair that it has to have a concrete foundation to rest on and has to be fired by electricity from a distance by a special corps of engineers. To this fact must be added that all accounts agree in placing the German general regimental rifle markmanship extraordinarily low; if current accounts are true the Germans when in massed formation do not even bring their weapons to the shoulder but let them off at the hip, trusting that such a sheet of lead will do some good somewhere. The consequence is that on the side of the French most of the wounds are shrapnel and shell wounds, and very serious affairs they are, many of them. A straight hit with a long, slender, sharp-pointed bullet from a modern rifle, if it doesn't kill you outright, is apt to heal up in a fashion that is altogether disconcerting. I know of two men in one small ward of eight, here in Paris, both shot right through the gastric region, who recovered in the simplest manner possible. These missiles, owing to friction in the gun-barrel and their high velocity, appear to be aseptic; if then they hit the combatant straight, that is, end-on and without any ricochet, the wound is so small that the fibres of the tissues must come immediately back on themselves and produce spontaneous obliteration of the aperture. It does not seem possible to account for these frequent recoveries from abdominal wounds in any other way; to suppose that the bullet slips between the coils of the intestine seems untenable. Anyhow, numbers of these men are eating and up and about in a wonderfully short time. As for the thorax, you seem to be able to send balls through the lung very nearly with impunity, so readily do these patients recover.

When, however, we turn to shrapnel and shell wounds, the question becomes at once vastly more complex. The bullet wound, clean, and very often dressed with the soldier's emergency package, on the spot, is little exposed to infection, and as a rule, the projectile passes right through clothes or accoutrements without carrying anything with it into the wound. But the large, round, leaden ball of the shrapnel is not clean, often remains buried in the tissues on account of its low degree of propulsion, instead of passing right through, as the rifle bullet does, and carries with it into the depths of the tissues fragments of pretty much anything it meets. Both bullet and foreign tissues set up suppuration, and these wounds are often long in healing. The worst wounds of all are, of course, those made by jagged pieces of shell, which frequently burst on the ground and carry with them dirt and all manner of filth. Up to the present time I have not seen a single mention in any of the reports that I have read on these subjects of any bayonet wounds on the Allies' side. This struck me as so peculiar that I questioned the head of one of the important surgical ambulances here concerning the matter and was surprised to hear that not a single bayonet and only one sabre wound had as yet been received at his ambulance, one of 250 beds where only Allied wounded are brought, the Germans having to go to places under guard.

The number of the wounded in this war has far exceeded all anticipations, and for a while the medical organizations were somewhat overpowered. The prompt removal of the wounded from the actual field has been difficult on account of the intensity of the fire, and many are the doctors who have already laid down their lives in this way. The outcome of all this has been that a large number of the graver wounds have become badly infected, and that the mortality from tetanus, simple gangrene, gas-gangrene, and hospital rot, has been a very serious affair. At one time the cases of tetanus assumed almost alarming proportions, with a mortality of nearly 100 per cent.; one man saved one patient out of fourteen, another had "hopes" of bringing four through out of twenty, while a third lost all four of his. Measures have, however, now been perfected for better immediate care of these seriously wounded men before their evacuation to the hospital centers, as well as for the prompt use of serum in advance with all jagged and soiled wounds. The fortitude and philosophy of the Allies' wounded has attracted unanimous comment, and is one of the most serious warrants for the ultimate success of the allied cause; what mortal man can be got to put up with, without complaint, the apparently unnecessary hardships and dangers that many thousands of these brave soldiers have had to undergo, simply leaves one speechless.

C. K. AUSTIN, M.D.

PARIS, October 16, 1914.

The Reaction of Morelli in Tuberculous Pleural Exudates.—Mameli Zannini states that this reaction, which is similar to the Runéberg nitric acid test, is based upon the fact that mercury combines with different types of albumin and gives rise to corresponding metallic albuminates. The technique of the reaction is a simple one. A cylindrical glass vessel is filled with a saturated aqueous solution of corrosive sublimate. Into this there are introduced slowly three or four drops of the liquid to be examined. If this is an exudate there forms on the surface of the solution a yellowish annular coagulum of albuminate of mercury which adheres to the side of the glass. If the liquid to be examined is a transudate the coagulum falls to the bottom of the vessel in the form of fine flocculi. This is the negative reaction which occurs constantly in the case of tuberculous pleural exudates.—*Rivista Ospedaliera.*

4. Nervous Diseases in China. A. C. Reed.

1. Vaccine Therapy in Eye Diseases.—L. S. Medalia finds that the judicious use of vaccines in bacterial infections of the eye yields results superior to those of any other method of treatment. Autogenous vaccines should be used and the treatment should be begun before permanent damage to the eye occurs. In the case of infections of the anterior chamber, especially in hypopyon ulcers, repeated paracentesis, in addition to vaccine treatment, yields better results than when vaccines are used alone. Small and oft-repeated doses are not followed by a marked negative phase and minimize the chance of a possible setback, both of which may occur if too big a dose is employed. The use of vaccines is of value in preoperative immunization. Vaccines are of particular value in cataract operations when the conjunctiva contains bacteria that cannot be eradicated in the ordinary way. Bacteriological examination in connection with prophylactic immunization prior to cataract operations seems to be the logical method of procedure and largely obviates the risk of postoperative infections.

2. Enuresis.—A. B. Schwartz notes that the good results and the failures in the treatment of the 226 cases of this condition that he had under observation are similar to those reported by other writers, and a study of these results leads one to the conclusion that the cause of enuresis in children is not the same in every instance. In some instances the nervous element plays a part, and in other instances faulty habits. Local irritation from any source is a predisposing cause. Excessive fluids result in a greater secretion of urine, while too little fluid results in a concentrated urine, which, whether it contains crystals or not, may irritate the base of the bladder and cause the desire for frequent micturition. Enlarged tonsils and adenoids, in the author's experience, have no connection with enuresis, neither have digestive disturbances, but possibly constipation is a predisposing factor.

1. Muscle-Bound Feet. — R. A. Hibbs defines a muscle-bound foot as primarily one in which dorsal flexion at the ankle joint is limited to an angle of ninety degrees or more by a short calf muscle. Dorsal flexion of the foot at the ankle joint should be to an angle of eighty or seventy degrees to the leg. This allows for the free swing of the tibia forward over the articular surface of the astragalus to the limit established by the change of the center of gravity. This causes the distribution of the weight through the foot in a constantly changing direction, makes possible the proper rest periods of the calf muscle, and insures the proper action and development of the opposing muscles and of the intrinsic muscles of the foot. When dorsal flexion is limited by a short calf to an angle of ninety degrees or more, the stride is shortened, the contraction of the calf is more frequent, and its rest periods are shortened. Or else, if the stride is not shortened, when the tibia reaches the limit of its swing forward over the articular surface of the astragalus established by the short calf, tension is made upon the muscle and it contracts, elevating the heel. The muscle is held in a state of contraction for a longer period of time, and it also suffers somewhat from tension made upon it. Its contraction is made in response to that tension, rather than to an impulse originating in the central nervous system, excited by a change in the center of gravity. The heel, being held elevated for so long a period, with the weight borne upon the distal ends of the metatarsal bones, adds the important element of footstrain. The circulation of the blood in the foot and leg is affected, because its perfect accomplishment depends to a very important degree upon normal freedom of the muscle action. Evidence of this disturbance is shown by a cold and clammy condition of the skin, excessive perspiration, feelings of heaviness and numbness, and a slight varicose condition of the veins of the calf. The gait produced by feet in such a condition must of necessity have an unfavorable effect upon the nervous system, because there is an overproduction of those waste products of muscle action which cause fatigue and muscle tension and affect the nerve ends in the fibers of the calf muscles by the impairment of the circulation, and so give rise to footstrain. Evidence of this is given in the fact that all these patients suffer from excessive fatigue. A certain amount of relief is obtained from exercise and massage, while properly fitting plates often relieve footstrain and hold the foot in a better relation to the leg. High-heeled shoes are more comfortable, and walking with a slightly bent knee is less fatiguing. It is impossible, however, to give permanent relief until the limit to dorsal flexion is removed and the normal muscle balance restored. This should be done early, before the changes in the foot have taken place and before the nervous system has been affected. The removal of the limit to dorsal flexion must be accomplished by some method which at the same time inhibits the function of the calf, after walking is resumed, long enough to allow the opposing anterior leg muscles to develop. Otherwise muscle balance will not be restored and no permanent good will be accomplished. Lengthening the tendo Achillis fulfills these conditions perfectly. It removes at once the limit to dorsal flexion and at the same time inhibits the function of the calf for from two to three months in children and four to six months in adults, giving abundant time for the proper development of the opposing muscles and the intrinsic muscles of the foot, and for the complete restoration of normal muscle balance.

2. Eventration of the Diaphragm.—M. Manges and H. Wessler state that eventration of the diaphragm is a comparatively rare condition in which the diaphragm, owing to extreme atrophy, succumbs to the pressure of the stomach and the intestines beneath it and, together with them, is displaced into the thoracic cavity. Anatomically, and from the point of view of morbid physiology, this differs only from a true diaphragmatic hernia in that, in the former the atrophied remains of the diaphragm are interposed between the lungs and intestines. In most cases the diaphragm seems to have entirely lost its function of contraction. The author reports two cases of this condition. The first case illustrates a common symptom complex. Under the influence of trauma or unusual distention of the abdominal viscera with gas, the already weak-

ened and stretched diaphragm is subjected to a further injury and the patient experiences a respiratory crisis very much like that which occurs in a sudden pneumothorax or in the onset of a pleurisy, viz., dyspnea, pain, cyanosis, and cough, symptoms which probably depend on the extreme displacement of the heart and bloodvessels and the resulting interference with the circulation. In their physical signs also, these attacks closely simulate pleurisy and pneumothorax; the signs comprise loud or dull tympany over the chest, immobility of the chest in respiration, succussion (due to the distended stomach) and dextrocardia. So frequent and striking is this association of symptoms, that not infrequently these cases are aspirated for fluid, a procedure not devoid of the danger of perforating the distended stomach. These crises are followed for a longer or shorter period by sticking pains in the back, and dyspnea and palpitation on exertion, until they are succeeded by another acute attack. In the gastrointestinal type, owing to the chronic dilatation of the stomach and also to periodical partial obstruction of the splenic colon in the cul-de-sac of the atrophic diaphragm, the patient may suffer from dyspepsia and recurring attacks of intestinal obstruction. If these symptoms are combined with a loss of weight and a severe anemia, as occurred in the second case, it is easy to see how a suspicion of carcinoma may be entertained. In this case the gastrointestinal symptoms were preceded for some years by definite cardiac symptoms which were attributable to the extreme dextrocardia which was here present. From the point of view of treatment, the differential diagnosis between diaphragmatic hernia and eventration is of practical importance. The former condition is amenable to operative treatment, which may become urgent in the case of intestinal obstruction. The treatment of eventration, on the other hand, can only be palliative. It is not possible to do anything to restore the function of a completely atrophic diaphragm. On the other hand, it is evident that anything which will increase intra-abdominal pressure will add to the difficulties of the already displaced diaphragm. It would seem rational to put patients suffering from eventration in consequence of a defective or atrophied diaphragm on a diet in which the fattening elements of the food are restricted, and to avoid such foods which by their fermentation would give rise to flatulence.

3. **Tuberculosis of the Conjunctiva.**—W. T. Shoemaker points out that this condition is an infective granuloma affecting the conjunctival tissue, whether bulbar or palpebral, and is due to the local multiplication of the *Bacillus tuberculosis*, and to the action of the toxins it elaborates. The presence of the tubercle bacillus is held to be indispensable for the existence of tuberculous conjunctivitis, and its demonstration absolutely essential for a certain diagnosis. The importance of laboratory investigation, therefore, in all suspected cases and in many cases thought to be other than tuberculous, is apparent. For this reason it seems probable that tuberculosis of the conjunctiva is perhaps not so rare as general records show, many cases escaping detection and falling under one of many other diagnoses. The treatment of tuberculous conjunctivitis includes the various measures used for tuberculosis, general or local. Tuberculin, *x*-ray, and radium are the newer remedies and all have given favorable results in the hands of their advocates. Cauterization, curettage, excision, and local applications of many kinds have also been of use. Certain cases can be cured, but Shoemaker says that the disease must always be regarded as very serious and the prognosis as most unfavorable.

5. **Myositis Ossificans Following a Single Trauma.**—P. Oliver notes that this malady results from a severe traumatism such as the kick of a horse, a blow from a sharp-cornered object, or dislocation of the elbow, without break in the skin or subsequent suppuration. Nearly all cases occur in the brachialis anticus or the quadriceps extensor, rarely in other muscles. It is found most commonly in vigorous middle-aged men. Porter and Quinby state that it is most commonly a result of posterior dislocation of the elbow. Machol records sixteen cases following the immediate reposition of uncomplicated posterior elbow dislocation and says that more than one half of the cases at the elbow follow this injury. Frangenheim states that aside from this variety of dislocation, it has been known to occur but once in the subclavius following clavicle dislocation, and once in the subscapularis following humerus dislocation. Schultz collected 233 cases from records in the German army during ten years, and in all but three the new bone was in either the quadriceps extensor or the brachialis anticus muscles. The essential character of the process is the formation of typical spongy bone intimately incorporated in the muscle. At an early stage it is cartilaginous, varying greatly in extent and shape. In the arm it may involve the origin, middle or entire brachialis anticus muscle and often the periarticular structures. The most typical growth is a somewhat tapering piece of bone in the brachialis anticus attached by a narrow stem to the tip of the coronoid process of the ulna. But as a rule, the new bone is not firmly attached to the humerus or ulna. Of fifty-six cases at the elbow collected by Cahier, in twenty-six it was entirely movable, four pedicled, sixteen attached to the capsule, and one at first movable but later fixed.

7. **The Four Common Types of Heart-Disease.**—By R. C. Cabot. (See MEDICAL RECORD, June 27, 1914, page 1190.)

8. **Cardiorenal Disease.**—A. Stengel states that among the pathological conditions included in the term are three important groups: (1) primary valvular or

myocardial disease with secondary renal disease; (2) primary arterial or arteriolar disease with secondary renal and myocardial disease, and (3) primary renal disease with secondary myocardial and vascular disease. The group of cases included under the term cardiorenal diseases presents a varied symptomatic picture. Dyspnea, continuous or paroxysmal, high arterial tension, a pallid (arteriosclerotic or nephritic) appearance, palpitations, and sometimes substernal or precordial pain, sometimes edema of the extremities and effusions in the serous cavities, headaches, neuralgias and various cerebral disturbances, polyuria or reduction in the amount of urine, disturbances of vision, gastrointestinal disorders and heaviness, stupor, or even coma are among the prominent symptoms encountered. Physical examination discloses enlargement of the heart and evidences of cardiac weakness, sclerosis of the vessels, albuminuria and casts in varying degrees of prominence. As the disease advances, increasing evidence of circulatory embarrassment on the one hand or of renal inadequacy on the other hand manifest themselves, and the termination may be quite clearly a circulatory or renal death; but even up to the last there may be difficulty in determining the major fault. Particularly true is this in patients dying in coma when the possibilities of cerebral hemorrhage and uremia seem equally balanced, and in cases of severe paroxysmal dyspnea. From the very beginning, however, the physician finds it necessary to make a decision and direct treatment accordingly. Of the three groups of pathological conditions comprised under the general heading of cardiorenal disease, that which most frequently presents a clinical history of value is the combination of valvular or myocardial disease with secondary nephritis. In Group 1, especially in valvular cases, cardiac enlargement and particularly enlargement toward the right is significant. A second point of importance in the physical examination is the character of the murmur heard over the heart. In primary mitral regurgitation, the systolic murmur always occurs in the early part of the systole, sometimes so early that it quite overshadows the first heart sound; while in the mitral leakage following continued high tension, the murmur is so late in systole that the first sound is heard an appreciable interval before the murmur and the second heart sound follows immediately after the murmur. Among the functional tests in use at the present day are the following: the phloridzin test, the determination of the time relations and quantity of excretion of potassium iodide, sodium chloride, milk-sugar, indigo-carmine and phenolsulphonephthalein. The marked response of primary cardiac cases to digitalis and other cardiac tonics is sometimes fairly diagnostic in significance. Rarely ever does one see anything approaching this response in the other groups, even when secondary cardiac failure has become a marked feature. In the second group one finds the most satisfactory results from the diuretics of the caffeine group. The same enormous diuretic effect from caffeine or theobromine salts is rarely seen in other cases. In the third group diaphoresis by means of baths, pilocarpine, etc., sometimes yields satisfactory results to an extent far more striking than in the other two groups.

1. Cancer of the Duodenum and Small Intestines.—Sir John Bland-Sutton points out that a study of the effects produced by cancer of the duodenum shows that the time-honored division of this section of the small intestine into first, second, and third parts is of little use for the purposes of clinical medicine. It is more convenient, following Sherren, to call the portion above the bile papilla the supraampullary segment, the portion containing the bile papilla, the ampullary, and the remainder the infraampullary segment. Cancer arising in the duodenal mucous membrane around the bile papilla is known as circumampullary cancer, in order to distinguish it from cancer arising in the ampulla or in the common bile-duct, but the three varieties lead to obstruction of the bile-duct, jaundice, and distention of the gall-bladder. There can be little doubt that cancer of this section of the duodenum would often escape detection if it were not for the obstruction it offer to the flow of bile from the common duct. It is very difficult to distinguish clinically between circumampullary cancer, ampullary cancer, and malignant disease of the head of the pancreas, for all give rise to obstructive jaundice, often associated with an overdistended gall-bladder. Primary carcinoma of the ampulla is interesting in itself and exhibits some remarkable peculiarities. Nowhere in the body does so small a growth lead to such grave interference with digestion. A cancerous growth, sometimes no larger than a cherry, will block the outflow of bile and pancreatic juice, and cause intense jaundice and great emaciation by interfering with digestion in consequence of the obstruction to the outflow of pancreatic juice. The three clinical signs of cancer of the ampulla are painlessness, intense jaundice, and great emaciation. The pathological features of the disease are its slight tendency to infiltrate surrounding structures, the infrequency of dissemination, and the enormous dilatation of the main bile-ducts and the gall-bladder. A feature of cancer of the ampulla which distinguishes it from cancer of the gall-bladder is the infrequency with which it is associated with gallstones. The transverse or infraampullary duodenum is the common place for duodenal cancer. The symptoms associated with it are like those set up by cancer of the pylorus, but the vomited matter contains bile and pancreatic juice and is sometimes very offensive. The simple tumors arising in the intestinal walls may be lipomas; some are described as myomas, and many as sarcomas, but whatever the structure the constant propulsive efforts of the intestine tend to force the tumor towards the lumen of the bowel until it projects within it, covered merely by a layer of mucous membrane. The danger to be feared from such a tumor is invagination or intussusception of the gut, for the tumor acting as a foreign body is urged along the bowel, and being fixed to the bowel wall drags it in and produces an intussusception which, if unrelieved by art or the timely sloughing of the intussusceptum, ends in fatal obstruction. Cancer of the small intestine may arise in an accessory pancreas. Small detached masses of pancreatic tissue have been detected in the stomach near the pylorus and in the duodenum; they may be situated in the mucosa, the muscularis mucosa, or in the muscular layer of the intestine, and measure 3 or 4 centimeters in diameter. An accessory pancreas is occasionally situated at the apex of the diverticulum. The ileocecal valve, notwithstanding its narrowness, is rarely attacked by morbid growths. The hyperplastic form of intestinal tuberculosis is most common in the cecum and cecal end of the ileum. It differs from other varieties of tuberculous disease in that the lesion is not destructive and leads to an increase in the bulk of the part affected. From the operative point of view the

distinction between cancer and hyperplastic tubercle is not important, for the treatment in both conditions is the same—excision; but the distinction is a matter of great concern in regard to prognosis. Cancer and hyperplastic tubercle left to run their course end fatally, but the latter is curable by excision. Melanosis is a morbid condition of the mucous membrane of the colon that has received little attention. Although the pigmentation begins, as a rule, at the ileocecal valve and extends to the anus, cases have been observed in which it does not involve the whole length of the colon. When the colic membrane is involved throughout the pigmentation is discoverable at the anus by means of a speculum. The condition is mainly a clinical curiosity, but if detected in the course of a clinical examination it might have an undue significance attached to it.

3. Incontinence of Urine in Women.—D. Newman notes that the most common causes of simple incontinence of urine in women—that is to say, loss of control unassociated with disease of the bladder or the urethra—are injury received during parturition and overdistention of the urethra and neck of the bladder by instruments. As a result of these injuries a secondary cystitis or urethritis may be set up which aggravates the suffering considerably. There are other cases where no history of traumatism can be discovered. The former are more amenable to surgical treatment than the latter, but even these may be much improved by operation.

5. Mediastinal Pleural Effusion.—A. Rose points out that extensive pleural effusion limited to the mediastinum is a rare disease. He reports the case of a patient 52 years of age who gave a history of gradually increasing weakness, wasting, and dyspnea of at least twelve months' duration. On postmortem examination it was found that the right lung was adherent to the chest wall all around. In a cavity bounded by the diaphragm below, the mediastinal pleura internally, and the compressed lung in other directions, there were 80 ounces of serous fluid which coagulated spontaneously. The principal points of interest in this case were the position and large amount of the effusion, the slight inconvenience caused to the patient during the many months it must have taken to accumulate, and the almost complete absence of pressure symptoms. The postmortem findings suggest that the effusion was originally an encysted diaphragmatic one, and that its extension to the mediastinum occurred comparatively late. The lung, being tuberculous and fixed, would offer less resistance to the pressure of the fluid than offered by the mediastinal contents and the comparatively healthy left lung.

3. Pinewood Sawdust as a Surgical Dressing.—C. W. Cathcart states that sawdust has been used from time to time by many surgeons as a surgical dressing, but its merits do not yet seem to be appreciated as they deserve. The sawdust from various kinds of pinewood has given good results. The softer kinds are the best, being more absorbent, while the harder kinds, although less absorbent, have the advantage of containing more resinous material. The method of preparation the author has found useful is the following: Two large standard wire sieves are required—No. 8, that is, eight threads per inch, and No. 40, that is, forty threads per inch. In order to reject the coarse fragments the sawdust, as obtained from the sawmill, is passed through No. 8 sieve and allowed to fall on to No. 40. It is then well shaken and rubbed on No. 40, and the very fine particles which pass through are discarded, because they would escape too readily from the prepared pads and cause an inconvenient dust. The sawdust which remains on No. 40 sieve is put into a box or sacks made of butter muslin, which are filled about two-thirds full with the sifted sawdust, and then closed with a colored thread. The filled bags or pads are sterilized by steam in the same manner as other dressings. After use the colored thread is withdrawn, the sawdust thrown away, and the bag washed, boiled, and dried for future use. Besides the advantage of cheapness, and the relative ease with which it may be obtained, sawdust is very absorbent. It is well adapted for civil or stationary military hospitals.

5. The Outlook in Epilepsy.—W. A. Turner states that when a case of epilepsy first comes under observation certain features are present by which the outlook may be surmised. As features of a favorable character may be mentioned the commencement of the disease between the ages of 16 and 20, especially if a hereditary history is obtained, and some obvious exciting cause for the disease is present; the commencement of the disease after 40 or 45 years of age provided organic disease of the brain can be eliminated; the infrequent occurrence of the seizures, and the absence of any obvious mental impairment or well marked stigmata of degeneration. In contradistinction to the above mentioned types of epilepsy, there is the incurable, chronic, or confirmed type, which finds its way eventually into institutions for epileptics. Epileptic dementia is revealed by all grades of mental deficiency, from a mere defect of memory, especially for recent events, up to pronounced dementia. Although an integral part of the disease it may be modified to some extent by the duration, the frequency, and the character of the seizures. Once the mental condition has become materially affected in the direction of dementia, the outlook as regards any real amelioration is unfavorable, although the fits may be kept in abeyance over long periods by sedative remedies.

Atonia Gastroduodenalis Acuta.—Melchior writes of the so-called arteriomesenteric duodenal occlusion. After discussing certain anatomical and physiological conditions due to the erect position of mankind aided or not by compression of the waist he portrays the manner in which a quasi-physiological condition may pass into a pathological entity. Sinking into the lesser pelvis of the small intestine makes traction upon the root of the mesentery, so that simple compression by the latter becomes sudden occlusion with resulting acute duodenal ileus. In 1856 Wunderlich first isolated this condition. The partial blocking of the lower portion of the duodenum by the pedicle of the mesentery caused an extreme distention and stasis of the stomach with fatal termination. The clinical picture soon became known through the labors of many pathologists and clinicians, and is fairly constant. The patient vomits a vast quantity of watery fluid, brilliantly colored with bile. Examination shows a soft abdomen, although there seems to be some fullness in the epigastric region. The chances are that the medical man will have the patient's stomach washed out but the effect of this procedure will

be the reverse of that anticipated. The patient will continue to vomit watery bile, and perhaps later blood. The atony of the stomach has now become extreme, so that the dilated organ distends the entire abdomen, and the general condition becomes very threatening. Nothing passes by the rectum, extreme thirst sets in and general peritonitis is closely simulated. Death may occur in from a few days to two weeks. Upon making an autopsy the physician is surprised to find that peritonitis is absent. The stomach, pylorus and duodenum are immensely distended down to the duodenojejunal junction at which the root of the mesentery is pressing. At the moment at which this pressure is relieved by the elevation of the mesentery the contents stagnated above enter the jejunum. This condition rarely occurs save in broken down subjects, especially when these are bedridden. In a number of cases posture alone has resolved this condition—knee, elbow or simple abdominal. This occlusion differs from an ordinary strangulation ileus in the absence of reaction, the constant fluid being only a narrow ring of necrotic mucosa. The article will be continued.

Supernumerary Kidneys.—Neckarsulmer reports a case of supernumerary left kidney encountered accidentally in an autopsy upon an infant dead of bronchopneumonia following measles. This organ showed incomplete development and must be classed as rudimentary. The right kidney and both adrenals were normal throughout. The left kidney was placed somewhat lower than the right and was shorter, with a ureter normal otherwise but shorter than its fellow. The third kidney, compressed into a flattened cone, adhered to the upper pole of the left kidney and terminated in a ureter which ended as a cul-de-sac in the vesical wall. The organ could have shown no functional activity; had it done so only cyst-formation could have resulted. In a case parallel with the author's the supernumerary rudimentary kidney had become the seat of an adenoma. It is evident that this abnormality is related to double kidney with two normally functioning ureters. In 1891 Palma compiled the recorded cases of supernumerary kidney; and up to date at least five cases of this sort are upon record in which individuals have possessed three full value kidneys. In other cases the data are not sufficiently compendious to determine the exact nature of the third kidney. In the author's case and another parallel with it the data are sufficiently complete for a diagnosis of rudimentary non-functioning third kidney.

An Accessory Article of Diet for Athletes and Soldiers.—Roeder announces as a food stimulant for distance runners and marching troops a combination of malt extract and yerba maté or Paraguay tea (or Peruvian tea). The latter is described at great length. Two great advantages are claimed for it, to wit: it possesses a property of quenching thirst and can replace alcohol successfully. In addition to the classes of people already given which should benefit from its use the author further mentions school children whose intensive mental and physical activities are strengthened thereby. Naturally so excellent and promising a resource is to be marketed as a proprietary. The author seems unaware that his combination is not entirely new, although perhaps never recommended for the indications stated in the article. Nor does he refer to the fact that Paraguay tea was extensively recommended over a generation ago for sick headaches and similar affections, despite which advertisement it sank into desuetude.

The First War Casualties in Reserve Hospital B. Munich.—Krecke states that this institution which has 1100 beds received its first batch of wounded on August 20-21, its second on the 23d and its third on the 25th. The troops concerned were fighting in Alsatia and the first to arrive were but slightly wounded. The later arrivals, however, had participated in a heavy pitched battle and were in part severe sufferers. They had been lodged for the first night in extemporized shacks, or in barns and churches, starting for Munich on the following day. An *x*-ray apparatus was ready for the photography of all bone traumatisms, with Sielmann, an expert, in charge. The condition of the wounded was in general excellent. As a rule the first immobilization for bone injuries were very satisfactory. Even in fractures of the thigh there was no severe reaction. Bullet wounds of the soft parts were thoroughly harmless. Wounds made by fragments of shells were of course shocking especially when the tissues of the face were involved. The havoc wrought here is sufficient to exclude any idea of humane warfare. Naturally many of those thus injured never reach the Reserve hospitals. These lesions produced relatively slight reaction in the tissues. Wounds of the skull, thorax, and abdomen were not very numerous, while the reverse is the case in regard to the extremities, the terminal segments suffering notably. Lesions of bone everywhere showed the greatest variety and absence of type especially when fragments of shell were at fault. The bearing of the men was heroic, they showing great firmness and stoicism. Not one repined or bemoaned his lot.

Observations in a Field Hospital.—Klaussner, surgeon in a Bavarian Army Corps gives some of his experiences in a letter to the Military Supplement. A temporary addition to a garrison hospital was erected, with accommodation all told for the 1,500 wounded who were treated during August 12-14. Dressings were made day and night. The soldiers who were transportable had to give way to the newly wounded. Then came the order, on tactical grounds, to abandon the field hospital, and the wounded had to be conveyed to a school house, in which an operating room was improvised. Later a French garrison hospital with its medical staff fell into the hands of the Germans, who took over the work. The conditions were universally bad, as the gas supply had been cut off. The odors of gangrene and miscellaneous filth were intolerable. The French soldiers appreciated what was done for them as sanitary restitution was gradually brought about and their remarks about their own medical staff were not exactly flattering. Klaussner's letter bears many marks of censorship, names of places and other data of identification being stricken out. In the present communication he announces the postponement of his account of the wounds dressed.

Tribromonaphthol as a Disinfectant.—The present number of the *Wochenschrift* contains no less than three articles on this substance which, like nearly all innovations in Germany, is being sold under a proprietary name. Bechhold, one of Ehrlich's staff, terms it—under its natural designation—a semispecific disinfectant. The specific disinfectants must according to this nomenclature be lysins or agglutinins, while a half specific is one which can exert a quasi-specific action on certain well known pathogenic bacteria. The same property is seen in the indifference of the substance toward other activities, *i.e.* it does not exert any influence on leucocytosis, and in fact is practically devoid of toxicity. On a wound surface it is non-irritating, yet at the same time acts as an antiseptic and proliferant. In a special article Professor Leser pronounces tribromonaphthol interesting to the surgeon because of its nontoxicity, freedom from odor, high disinfectant activity

against the pyogenics, etc. A disadvantage is the unstable character of its solutions which hardly maintain their integrity for more than 24 hours. Dr. Ziegler states that he has been testing the remedy since 1909. It is a true germicide in 1 per cent. solutions (its power over spores is not mentioned) and even in very great dilution is able to inhibit bacterial proliferation, and is well adapted for hand disinfection and for sterilization of the skin of an operative field. For the latter purpose used in a 5 per cent. concentration in alcohol it can replace tincture of iodine.

Diphtheria Prophylaxis in a Settlement for Children.—Karl Kassowitz, of von Pirquet's clinic in Vienna evidently does not share the views of his recently deceased namesake on the specific treatment of diphtheria. As the result of successful jugulation of an institutional epidemic he lays down the principles to be carried out under these circumstances. All exposed persons should be tested at once with cultural methods. The nasal discharges and tonsillar plugs, should be used further in guinea pig inoculations. In the interim relative isolation is carried out after positive tests, special isolation during treatment and until tests become negative. The institute or school building must of course be closed for disinfection. Carriers should have a diagnostic intracutaneous test with diphtheria toxin, and wherever this is positive serum treatment is practised. Carriers should be under ambulatory control until all tests have been repeatedly shown to be negative. As a local remedy, prophylactic or remedial, hydrogen peroxide cannot be excelled. In the kindergarten settlement a child was found ill with diphtheria and removed to a hospital and before the author was given charge new cases continued to appear at brief intervals. Fifty-two children of this group were now systematically tested and eight were found to be carriers, but of this number only three reacted positively to the intracutaneous test with diphtheria toxin and these received prophylactic serum injections.

Cancer Problems.—Von Hansemann divides cancer investigation into chronological periods, the earliest of which he terms the morphological (histomorphological). As a result of the strictly scientific work of this period we are able today to make with relative certainty a diagnosis of malignancy from the inspection of a bit of tissue removed *in vivo*. The second chronological period is termed the etiological, and unlike its predecessor it has not been characterized by strict scientific methods and forms a rather gloomy chapter in the evolution of medical knowledge. It seems clear that there is no single cause of cancer. Various factors can singly produce the same result and a single factor can produce different results. The most recent accessions are the most valuable. We know that *x*-rays alone can produce cancer in man, just as we know that certain parasites cause it in the stomach of the rat. The same parasites also cause in some rat individuals benign growths, just as in others they are unable to produce tumors of any sort. The third sequential period is the experimental from which much has been learned concerning certain animal tumors. It has doubtless been an error to devote so much time to the Jensen mouse-tumor which is not cancerous in the strict sense; and more progress might have resulted had Hanau's experiments with true rat cancer been followed up. The vast body of positive data built up in connection with the Jensen tumors unfortunately has not aided thus far in solving the problems of true human cancer. Much more promising is the line of research which is being conducted in animals by Fibiger who deals only with true carcinoma. The fourth and last period now in course of evolution may be termed the therapeutic. In the strict sense, neither the knife nor the *x*-rays constitutes a cure. Since true carcinoma never undergoes spontaneous recovery, the outlook for a true remedy is highly unpromising. For unless a disease process can show a tendency however slight to self-limitation and spontaneous cure it is a principle in therapeutics that it is incurable in the strict sense.

Diagnosis of Smallpox.—Risel intimates that our knowledge of the clinical course of variola is derived to a considerable extent from study of the pandemic of the disease which followed the Franco-Prussian war. The vaccination laws of 1874 then suppressed the disease to such an extent that but slight opportunity for its study has since been afforded. The teaching at the time was that the distribution of the rash was determined by the areas of the skin most exposed to mechanical and chemical irritation. Since that period variola has been extensively studied at the London Smallpox Hospital, especially during the epidemic of 1902 and the teaching of Curschmann as to the distribution of the rash has been abundantly confirmed, even experimentally. During the incubation period the application to the skin of an irritant like mustard or iodine will bring out a crop of pocks narrowly limited to the irritated area. In badly nourished nurslings the folds in the integument form areas of predilection. In the covered areas the rash occurs by preference where pressure and friction are found. In a general way the more intense the irritation the thicker the rash, and *vice versa*. This teaching, be it remembered, applies to genuine smallpox, as it occurs in those who have not acquired immunity from previous attacks or from vaccination. In varioloid vaccinia, varicella, etc., no such law is in operation. The eruption appears on protected localities—the flanks, loins, etc. The law of localization in genuine variola affects the distribution of the pocks but does not apply to the socalled proruptions seen during the prolonged incubation period, and which are toxic erythemas or in very severe cases petechial. This early rash bears a considerable resemblance to measles in its localization, as it spares the face, but is extremely fugacious in character. It may be studied in subjects who have been quarantined after exposure, and with the petechial form possesses prognostic significance, for the latter forecasts the hemorrhagic type of variola. In the most deadly cases we see a solid, permanent erythema of the entire surface, including face and extremities, associated with petechiæ, death often occurring before the appearance of the pocks. The ability of varicella to mimic variola is marked, even for genuine variola, and it is difficult to make a dictum in regard to the latter that cannot be realized in some degree or exceptional case of the former. The most trustworthy criteria, such as inoculation of the rabbit's cornea, are not adapted to common use.

Salvarsan Infusion in Scarlatina.—Glaser cites many cases in which authors have sought in salvarsan a remedy capable of influencing the course of scarlet fever. He himself has employed it in 42 patients. Three of these were doomed in advance as far as customary remedies are concerned and intravenous infusion of salvarsan could not stay the end. In a series of 15 cases with doubtful prognosis, the patients all having pharyngeal diphtheroid, the drug brought about a sudden fall of temperature and the diphtheroid appeared to undergo involution in all but two cases which ended fatally. The administration of salvarsan was followed by a severe general reaction which may have influenced unfavorably the two cases in which no benefit resulted.

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

ACUTE RHEUMATISM AND CARDIAC COMPLICATIONS.

It is generally accepted that acute inflammatory rheumatism is an infectious disease and that the exciting cause is a microorganism which has been designated by some as *Diplococcus rheumaticus* or *Streptococcus rheumaticus*. There are a number of predisposing causes which create tendencies or fertile resting places for the cultivation of the microorganism.

Heredity is admitted as a predisposing cause, as it can be traced in about 30 per cent. of the cases according to various observers. The influence of heredity is especially marked when it is transmitted from both sides of the family. If one parent has had rheumatism, it does not follow by any means, that his child will suffer from it. On the other hand, if the applicant himself has had an attack, the probability of recurrence is greatly enhanced.

The disease is rare under five years of age, but from that time up to fifteen, it is found much more frequently. Its occurrence is rather steady through adult life after which the tendency weakens. As a rule, the earlier the age at which a primary attack occurs, the greater the likelihood of repeated attacks, the greater the severity and the liability to involvement of the heart.

Climate, season, and locality have considerable influence in the causation of the malady. It is more common and severe in changeable climates, especially where there is much dampness. The majority of cases are found in the autumn and spring. Damp localities or houses, especially those at low levels, favor outbreaks of the disease. Those following occupations calling for great muscular exertion with consequent fatigue and free perspiration, especially in places where there is exposure to draughts or strong winds, are more liable to attacks.

Diet, notwithstanding popular ideas to the contrary, has little to do in the causation of the trouble, and the so-called excess of uric acid or uric acid diathesis in the opinions of many competent judges is of little consequence as a predisposing factor.

The occurrence of endocarditis is an ever-present danger. The valves of the left side suffer more than those of the right. Simple endocarditis gives rise to few symptoms and it frequently happens that when an individual with a valvular lesion comes under observation for life insurance, he learns of its presence for the first time. Many mitral lesions exist for twenty years and more without discomfort or apparent changes. Just what percentage of cases in which a valve lesion, once established, goes on for long periods without a cardiac breakdown is unknown. The lesions in these cases, however, are usually a mere roughening or thickening of the tissues about the mitral valve with little or no leakage.

The extra mortality among policy-holders with a history of rheumatism is shown by the results of the Medico-Actuarial Mortality Committee in the table.

The table indicates that, when there has been an attack of acute rheumatism within five years, provision should be made for an extra mortality of at least 20 per cent. Rogers (Transactions of the Actuarial Society of America, Vol. XV, Par. I) states that, judging by his company's experience in risks to which a rigid selection was not applied, having been accepted as substandard on account of a history of acute rheumatism, provision for an extra mortality of 40 per cent. is necessary.

TABLE SHOWING THE EFFECT OF RHEUMATISM ON MORTALITY.

	Actual Deaths	Expected Deaths	Ratio of Actual to Expected Deaths
One attack within 2 years of application	118	348.49	120%
One attack between 2 and 5 years prior to application	551	458.92	121
Two or more attacks, the last within 2 years of application	106	86.48	123
Two or more attacks, the last between 2 and 5 years prior to application	57	52.40	109
An attack at an indefinite time in the past	168	155.91	108
One attack more than 5 years prior to application	63	57.93	109

Death from heart disease in the class represented in the tables at the younger ages at entry was about three times the normal. The mortality accompanying acute articular rheumatism was eight times the standard.

If the risks are carefully selected they may be accepted on the life plan when there has been a single uncomplicated attack previous to one or two years ago, as the medical officers may elect. In the event of two attacks prior to a year ago, the risk should be offered a rated-up or endowment policy. If there have been three or more outbreaks, the applicant should be rejected unless the date of the last attack is remote.

The examiner carries out an important task by eliciting a full history of each attack of acute inflammatory rheumatism and ascertaining as far as possible from the attending physician as to whether or not there was cardiac involvement. Furthermore, the examination of the heart and vessels should be undertaken with unusual care.

Questions by Medical Examiner—Evidence—Rules as to Rejection of Pregnant Women.—Relative to a false answer in a medical examiner's blank not avoiding a policy, though the blank, warranting the answers therein, was signed by applicant, sufficient doubt to require submission to the jury as to whether the question, Was she pregnant? was asked applicant, is raised in an action for the death benefit by the examiner's testimony that he was unable to say whether he asked her the question, and that he does not ask all the questions in the blank.

The rule of a benefit society that medical examiners shall reject a pregnant female applicant for membership, unless she signs a waiver of claims resulting from such condition, need not be in writing nor promulgated, to be within the rules, subject to all of which the application is, in terms, made.—Clark vs. North American Union, Michigan Supreme Court, 146 N. W. 336.

Age Limits.—The company showing acceptance of risks beyond the average age will have a higher mortality. The influence of age is very important. It has been shown that at 48 the mortality is lower than we have built our premiums upon, while after 50 the mortality is considerably higher. After 45 or 50 we must select more carefully. The lapse ratio will also affect the mortality.—Thomas W. Blackburn, secretary and counsel, American Life Convention.

Society Reports.

AMERICAN ELECTROTHERAPEUTIC ASSOCIATION.

Twenty-fourth Annual Meeting, Held at Battle Creek, Mich., September 15, 16, and 17, 1914.

THE PRESIDENT, DR. GEORGE E. PFAHLER OF PHILADELPHIA, IN THE CHAIR.

Presidential Address.—Dr. PFAHLER took as his subject "Electrothermic Coagulation or Excision and Deep Roentgen Therapy in the Treatment of Malignant Disease." This treatment consisted in a coagulation of all microscopical malignant disease by means of the d'Arsonval current carried between two poles locally. This was followed by deep Roentgenotherapy, with the most modern technique, consisting especially of deep penetrating rays, passed by cross fire through multiple areas of entrance. As much Roentgenotherapy should be used as would be used if depended upon alone. Twenty cases were reported.

Report of Committee on Induced Current, Including Alternating and High Frequency Currents and Apparatus.—Dr. FREDERIC DE KRAFT of New York, chairman, reported that the committee had taken up the question of the use of thermopenetration in the treatment of pulmonary tuberculosis. In marked congestion of the lungs from mitral disease tuberculosis was very rare. Therefore it would seem rational to produce a congestion in treating tuberculosis of the lungs. This could be accomplished by the high frequency current. At the tuberculosis camp of the Albany Hospital the employment of high frequency currents had given the best results of any special treatment that had been tried. The secretion of mucus was increased, and became of lighter consistency, and was more easily expectorated. The night sweats improved, the temperature dropped, the weight increased and the appetite improved.

Static Currents and Apparatus.—Dr. HERBERT F. PITCHER of Haverhill, Mass., made this report. He said there had been developed no new or improved method or apparatus during the past year, with one or two exceptions. Dr. E. C. Titus, a member of the committee, had conducted a series of experiments with different kinds of metals made into the form of tips which were inserted into a brush discharging stick. A new condenser static machine had been invented by Dr. Wommelsdorf which was said to be absolutely independent of atmospheric conditions. In the use of the static brush discharge the committee believed there should be a sharp distinction made between the "sputtering brush discharge" applied through the moistened wooden sticks and the "blue pencil discharge or flame" formed by an electrode of some resisting material with a sharp pointed metallic terminal.

In a separate report Dr. Pitcher took up the question as to whether static currents passed through the body. This had long been a mooted question. His conclusion was that the static current in its course from surface to surface, charging and discharging, always passed through instead of over the tissues of the human body. The actions and effects of static currents were energetically mechanical, exerting responses of all the tissues of the body which were capable of contracting when subjected to interrupted electro-static stimulation. Independent muscular excitation was another principle of action that must be conceded, though it had often been questioned. The action of the static current was directly upon the cell and did not depend for the induction of muscular contraction upon the complex action of the neuromuscular mechanism.

Phototherapy and Apparatus.—Dr. JOHN S. YATES of Paterson, N. J., said the dominant note in light therapy during the past year had been in the application of heliotherapy to the treatment of surgical tuberculosis. He quoted from an article by Henry Dietrich of Los Angeles in the *Journal of the American Medical Association*. He also discussed the use of artificial heliotherapy in the treatment of these cases. He discussed the treatment of cutaneous epithelioma by sunlight, and the use of ultra-violet light as a germicidal agent.

Radiography, Radiotherapy, and Apparatus.—Dr. H. M. IMBODEN of New York detailed the progress in this branch during the past year.

Mechanical Vibration Therapy, Exercise Therapy, and Apparatus.—Dr. MARY ARNOLD SNOW of New York Texas; *Vice-presidents*, Dr. A. B. Hirsh, Philadelphia, the efficacy of mechanical vibration as a remedial agent when scientifically employed to secure definite results. The simplicity of the apparatus used, the fact that the principles underlying its application were so well defined and that it was applicable to more conditions than massage, appealed to all who studied cause and effect and the most modern methods of securing best results with a conservation of time. Since the last meeting success in the treatment of splanchnic neurasthenia, cardiovascular conditions and asthma had confirmed the writer's previous experience.

Hydrotherapy, Thermotherapy, and Apparatus.—Dr. BYRON S. PRICE of New York said there was nothing new to report under this head. He read a report by Dr. Edgar A. Pole outlining the methods pursued at the Virginia Hot Springs. Dr. Price in his report discussed in detail the use of dry heat.

Dietetics.—Dr. J. W. TORBETT of Marlin, Texas, reported that the year's progress in dietetics had been made along the line of animal experimentation with the active principles of proteid food, that is, the amino acids of several varieties, to determine their influence on maintaining nutrition and promoting growth.

Standard Therapeutic Measures.—Dr. W. B. SNOW of New York made this report. The committee presented a report which was the result of a thorough investigation of all of the subjects pertaining to the methods, technique, and indications of the various forms of physical therapeutics. The report included a consideration of a careful investigation by the committee on the subjects of static electricity, high frequency currents, radiant light and heat, Roentgen ray, radium, mechanical, vibration, and the uses of heat and cold. The report comprised forty pages of carefully prepared matter considering the subjects briefly, the efforts of the committee having been to cover in a practical condensed form the outlines of the uses and indications of the subjects considered.

Dr. FREDERIC DE KRAFT of New York read a supplementary report on standardization of high frequency apparatus. He said the committee had found that by using four Leyden jars each of one gallon capacity a current was obtained of greater amplitude, in diathermy the heating occurred more quickly, and there appeared to be a quicker and more pronounced relief in conditions attended with great pain. The committee had also made some experiments to determine what voltage was best for charging the Leyden jars and had found that from 23,000 to 45,000 volts answered the purpose best.

Dr. E. C. TITUS of New York made a supplementary report outlining the requirements for the standardization of static machines.

Some Observations Concerning Blood Pressure.—Dr. J. W. TORBETT of Marlin, Texas, read this paper. Out of 1183 chronic cases seen during the first half of this year only six per cent. had hypertension. Only fifty per cent. of these had casts and albumin. At least ninety per cent. gave a history of having been large eaters of meats, pepper, vinegar, coffee, etc., and often users of tobacco, or having had chronic constipation. The cases were of two general classes: the toxic type in which there was little or no actual sclerosis. A moderate diet of bread, milk or butter, fruits, vegetables, cereals, and nuts, with eggs and breakfast bacon sparingly, with baths of any kind to make the skin act, medicine if needed for the kidneys and liver, fresh air, moderate exercise and sunshine, would relieve this class. The treatment should be repeated once or twice each year for safety. The other class of true sclerosis, except those very far advanced, might be helped a great deal. The diet and home treatment must be kept up the remainder of life. All nephritc cases were given apocynum, tincture of strophanthus, and compound lithiated sorghum. Autocondensation was one of the excellent aids in the treatment, but skin elimination and diet were paramount. A small percentage of the cases could not be reduced nermanently by any treatment without impairing their general health. So long as they led a proper life and the sphygmomanometer needle vibrated over three to five points while taking the blood pressure, these patients did not seem to be in any danger with the pressure even as high as 200 or more. Several cases of this type had been under observation for one to five years, and one for ten years. Improper relation of diet to exercise the writer believed to be an important causative factor.

A Study of Blood Pressure; Its Variations and Treatment.—Dr. WILLIAM MARTIN of Atlantic City, N. J., emphasized the importance of greater care in the daily

routine of blood pressure work, and particularly in the estimation of the three pressures, in order that we might show a full scientific knowledge of our work.

Indications for the Treatment of Inflammatory Conditions of the Spinal Cord and Meninges.—Dr. WILLIAM BENHAM SNOW of New York said the indications for the treatment of inflammatory conditions of the spinal cord and meninges were practically the same as for the treatment of inflammation elsewhere. The static modalities were capable of removing infiltration and exudation from the tissues of the spinal cord and meninges as from the other tissues of the body, thereby removing pressure and permitting the resumption of circulation and the restoration of the function of the parts. Early intervention by the employment of means for removing pressure was important to anticipate degeneration and prevent permanent impairment of function. The prognosis, therefore, as to complete restoration was relative to the promptness with which treatment was instituted and the character of the infection. In pyogenic and tubercular affections the static modalities would open up the lymphatic channels and extend the infection and were contraindicated. In these conditions the Roentgen ray with thermal penetration offered an invaluable means of relief.

The Practice of Medicine.—Dr. FREDERIC C. TICE of Roanoke, Va., in this paper gave a résumé of progress in medicine, with especial reference to diagnosis and electrotherapeutics.

The Treatment of Pellagra by the High-Frequency Current.—Dr. D. H. YATES of Madison, Fla., read this paper. He had treated about one hundred cases of pellagra. Out of this number he had lost six patients, one of whom had committed suicide. The cases lost were mostly in old people, and extreme cases. The cases were treated with the static current. The patient was placed on the insulated platform with the feet on the metal electrode, connected to the positive, with a crown electrode above the head connected to the negative side of the machine. The sliding rods were drawn out as far as possible without causing painful contraction of the muscles of the legs. The speed of the machine should be regulated so as to give about two hundred discharges at the spark gap per minute. The author thought that the action of the current in these cases was due to its influence on metabolism. Lantern slides were shown illustrating cases before and after treatment.

Elimination of Waste Products.—Dr. BYRON SPRAGUE PRICE, New York read an article, accompanied by illustrative cases, in which he pointed out the importance of thorough elimination, not only from the tissues into the blood stream, but from the latter through the glands to the excretory channels, of catabolic products in chronic diseases or conditions accompanied by depressed eliminative function. This object which was both difficult and important in certain types, could best be accomplished by the use of the oven bath (at a temperature of about 450° F.) following certain high potential and high frequency currents, in conjunction with other indicated measures.

Roentgen Therapy in the Treatment of Pulmonary Tuberculosis.—Dr. J. D. GIBSON of Denver said he was happy to announce that the literature on the subject of the *x*-ray treatment of pulmonary tuberculosis was very abundant to-day—quite a contrast to the time when he first brought the subject before the Association in 1901. He had followed out this method of treatment closely for thirteen years, and believed he was well within the bounds of truth in making the assertion that, in spite of all complications (hemorrhages, meningitis, and serious complications of the heart, kidneys, and stomach, and idiosyncrasies), eighty-five or ninety per cent. of all cases of pulmonary tuberculosis could be practically cured or made useful citizens.

The Continuous Static Currents.—Dr. CHARLES M. HAZEN of Richmond, Va., read this paper. His conclusions were as follows: Unidirectional currents may be expected to adjust to normal the polarities of the living cell or molecule. The clinical application of these currents is to all cell physiology and pathology, but especially to that of the nervous system, notably in neuritis and paralysis. The choice of these currents is the bipolar static, then unipolar, galvanism, the vacuum high frequency electrode, various other high frequency modalities, the static wave with short spark, and the rapid faradic.

The Effect of High-Potential Currents in the Treatment of Gout.—Dr. FREDERIC DE KRAFT of New York said that gout was more prevalent in the United States in recent years. There was always a condition of stasis in the affected toe. In the application of the d'Arsonval current the best apparatus was one with Leyden jars of large capacity. One should begin treatment with 1,000 milliamperes and gradually work up to 1,800 or 2,000 milliamperes. The treatment caused an increase of blood in the affected joint, facilitating phagocytosis. The phagocytes devoured the urate needles, removing the irritation, and the pain and swelling subsided. This was followed by an application of the blue pencil brush discharge.

A Further Consideration of Sacroiliac Conditions.—Dr. FRANK E. PECKHAM of Providence, R. I., read this paper. He emphasized the importance of finding out the cause in the individual case. He maintained that there was much more apt to be rigidity than relaxation. It was very important to get a careful history, to make a very careful physical examination, and to determine the etiology whenever possible.

The Postural Treatment of Chronic Arthritis.—Dr. L. T. SWAIN of Clifton Springs, N. Y., read this paper. He said that chronic arthritis was one of the most perplexing problems of modern medicine, and must be studied from all points of attack. In its diagnosis and treatment it was important to locate and eliminate all sources of infection, to study and improve metabolism, locally to treat the joints and muscles, and so to remodel the body by postural treatment that permanent improvement might be maintained.

Splanchnic Neurasthenia, Cause, Symptons, and Diagnosis.—Dr. MARY ARNOLD SNOW of New York said that the direct cause of splanchnic neurasthenia was a dilation of the splanchnic blood vessels, superinduced by some functional or chronic derangement, especially gastro-intestinal, resulting in a pathognemonic phenomenon consisting of an altered relation of the blood pressure and pulse, either or both, particularly of the blood pressure, taken both in the sitting and lying posture. The symptoms consisted of fatigue, disturbed mental attitude, dyspnea and gastro-intestinal disturbances. There was a disturbance of the relation between the pulse rate on sitting and lying. The indications for treatment were to lessen the splanchnic stasis and remove or treat the cause. The first indication could not be met by vibrating in the intervertebral spaces from the second to the fifth dorsal vertebrae inclusive. Other treatment consisted in vibration over the stomach, static wave current over the liver, the use of a correct abdominal support, increasing the lung expansion by means of exercises, and suitable diet.

Electrical and Mechanical Modalities in the Treatment of Affections of the Gastrointestinal Tract.—Dr. JOHN A. BURCH of Syracuse, N. Y., read this paper. He said very little was known about the use of physical and electrical modalities in the treatment of these conditions. During the past two years he had treated ten cases of simple anacidity by the intragastric application of the induced current. At the end of two months it was found that there was still no trace of free hydrochloric acid, and there was a total acidity of 7.9. However, five of these cases were improved clinically. Five very stubborn cases of achylia gastrica were submitted to electrical treatment by the d'Arsonval current with a vacuum tube applied over the stomach. Four of the patients improved very rapidly. Hyperchlorhydria and hypersecretion were made worse by electrical treatment. Patients with gastric and duodenal ulcer were often relieved of their distress by the simple application of the vacuum tube. Electricity, however, found its greatest usefulness in the treatment of gastroptosis and general viceroptosis. In these cases the writer used the slow sinusoidal current, with regulation of the mode of living and a suitable abdominal support.

The Nonsurgical Treatment of Intestinal Stasis.—Dr. FRED H. MORSE of Boston read this paper. Chronic intestinal stasis, whether local or general, might be in such a pathological condition following catarrhal inflammations as to demand surgery on account of adhesions and distortions which a careful diagnosis ought to determine. Many of the cases of gastroptosis and enteroptosis were freely movable about these disturbed areas and were curable by electrical and physical modalities, and if surgery were undertaken much harm was likely to result on account of dividing healthy muscular fiber. If, on the other hand, an adhesion or purulent condition existed much harm was bound to come by the usually advocated methods by physical apparatus in use by physicians. In doubtful diagnosis let *x*-ray photography decide. The sinusoidal current was the one treatment, and probably of greater efficiency in the majority

of cases than any other, though all forms were used.

Catarrhal Deafness Improved by the Yates Method, with Report of a Case.—Dr. A. B. HIRSH of Philadelphia reported the case of an unmarried woman of twenty-seven years who had a brief-period right-sided purulent otitis media in childhood after either parotitis, pertussis, or morbilli. Mild attacks of catarrhal appendicitis and of neurasthenia since then did not influence the case. Tonsillitis necessitated double tonsillectomy in 1908, but a previously noticed growing deafness grew worse. By 1912 she was forced to give up her clerical position in a life insurance company office. Head noises were aggravated, causing mental depression. The static brush discharge applied in January, 1914, to both ears according to Yates' method (*Journal of Advanced Therapeutics*, May, 1913) caused full removal of tinnitus and almost complete restoration of hearing. By May, 1914, she had resumed her regular office duties and joined freely in all church and other social duties.

Other papers read were: "The Influence of Electrical Applications upon Metabolism," Dr. J. H. Kellog, Battle Creek; "Infections of Adenoids and Tonsillar Tissues: Their Treatment, Preventive and Curative," Dr. S. St. John Wright, Akron, O.; "The Value of Movement Cure (Active and Passive) in Hernia and Uterine Displacements," Dr. Alice B. Condict, Orange, N. J.; "Intensifying Screen Technique," Dr. H. Threlkeld-Edwards, S. Bethlehem, Pa.; "Coolidge Tube Technique in Deep Roentgen Therapy," Dr. James T. Case, Battle Creek; "The Use of Diathermy in Acute and Chronic Bronchitis," Dr. A. J. Read, Battle Creek.

Officers.—The following officers are elected for the ensuing year: *President*, Dr. J. W. Torbett, Marlin, Texas; *Vice-Presidents*, Dr. A. B. Hirsch, Philadelphia, Dr. Curran Pope, Louisville, Ky., Dr. William Martin, Atlantic City, N. J., Dr. A. J. Hopkins, Pittsburgh, Dr. John S. Yates, Paterson, N. J.; *Secretary*, Dr. J. W. Travell, New York; *Treasurer*, Dr. Emil Heuel, New York; *Trustees*, Dr. George E. Pfahler, Philadelphia and Dr. Frederic de Kraft, New York; *Registrar*, Dr. Frederick M. Law, New York.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, Held June 2, 1914.

THE PRESIDENT, DR. SMITH ELY JELLIFFE, IN THE CHAIR.

Cases Treated by the Maloney Rest-Exercise Method.—Drs. I. ABRAHAMSON and ALBERT POLON presented these patients who had been treated in the Out-Patient Department of the Mt. Sinai Hospital. They were all ambulant cases, suffering from functional neuroses, and were presented to illustrate the value of the rest-exercise method of treatment, the technique of which had been given in detail in a paper on "Relief of States of High Mental, Vascular, and Muscular Tension," by Drs. W. J. M. A. Maloney and V. E. Sorapure, read at the meeting of this Society on March 3, 1914. The first patient was a girl, nine years old, who for seven months had suffered from a facial tic. The movements, which were persistent and annoying, consisted of extreme diviation of the eye-balls to one or the other side, followed by twitching of the nares and upper lip, by wrinkling of the forehead, and finally, by raising the index finger of the right hand to the nose, as though smelling it. She had been treated by various methods without relief. After two lessons by the Maloney rest-exercise method the movements had entirely disappeared, and the girl now showed no signs of the original affection.

The second case was a boy of twelve who had suffered from a facial tic which he had acquired by imitating some one in his class, and which became more pronounced under excitement. After a single lesson of 25 minutes' duration he was entirely relieved by the rest-exercise method.

The third case was that of a girl of 19, a stenographer and typist, who about five months ago, after an exciting occurrence, noticed that her left hand became weak and tremulous. These symptoms gradually extended to the corresponding lower limb and the girl was compelled to give up her work. For thirteen weeks she was under treatment by various methods without any benefit. After two treatments by the rest-exercise method her symptoms entirely disappeared and she was well enough to return to work.

The next patient was a boy of nine years who had suffered from blepharospasm, with more or less constant snuffling and hawking. This boy was still under treatment. Although he was much improved, there was still an occasional slight blinking of the right eye.

The next case was one of hysterical paraplegia in a boy of nine, which dated back three months and followed an attack of otitis media and facial erysipelas. According to the boy's history, the paraplegia came on suddenly; he was unable to stand or walk and was taken to the Beth Israel Hospital, where he remained for five weeks. He was then taken to his home, unimproved, and six weeks later he was carried to the Mt. Sinai Hospital, still completely paraplegic. The case was recognized as one of hysterical paraplegia, and after a single treatment by the rest-exercise method, the boy was able to walk home and had remained well ever since. In connection with this series of cases, Dr. Polon said he wished to emphasize the fact that by this method of treatment the patients were given self-reliance and confidence, which gave them a feeling that they could control themselves, and they were made to understand that it was through their own will power that they had accomplished these results.

Dr. A. A. BRILL said the cases shown by Dr. Polon were very interesting. He wished to call attention to the fact, however, that adult patients with tics usually gave a history of recurrent attacks dating back to childhood. The attacks came and went with more or less periodicity, and could be temporarily checked or mitigated by various methods of treatment, but they invariably recurred and he knew of no permanent cure. He recalled some cases that had been helped by psychoanalysis, but not permanently. Still, any method of treatment that would benefit these patients even temporarily should be encouraged.

Dr. BENJAMIN ROSENBLUTH said he had been giving attention to these tics for a number of years and he had come to the conclusion that most of them were referable to some occurrence in the conscious state which was repeated in the dream state. Acting on this theory, he had obtained very good results in the treatment of these patients by giving them drugs directed toward cutting out dreams, without paying any special attention to the patient's physical condition.

Dr. F. K. HALLOCK of Cromwell, Conn., asked Dr. Polon if he was familiar with the relaxation method of Anna Payson Call of Boston. Nearly twenty years ago this young woman began to treat neurasthenia and conditions of nervous hypertension by alternate exercise and relaxation movements. With the patient lying prone, she first relaxed the head, then the extremities, and finally rolled the body half way over and let it sag back in a state of complete relaxation. Dr. Hallock said he had employed this method for the relief of general neurasthenic conditions, and in many cases he had found it very satisfactory. His experience with it in tics had been very limited except as a general procedure for all persons of this type.

Dr. JELLIFFE said that even more remote than the relaxation method of treatment referred to by Dr. Hallock were those in vogue centuries ago in the time of Hippocrates and in the Æsculapian Temple, as well as among the Indian cults. An interesting historical perspective might be thrown upon the present cases in the light of the older methods. In what sense had the newer methods become more definite and precise?

Dr. POLON, in closing, said the most marked difference between this method and the types of relaxtion treatment employed in former times and still used in some clinics today in Berlin and elsewhere lay in the fact that they depended largely on suggestion and hypnosis, the idea being to dominate the patient without giving him any explanation as to cause and effect. By the method which had been employed in the series of cases shown here tonight the treatment rested upon a physiological basis which it was attempted to explain to the patient. The importance of these relaxation movements were impressed upon him, and they were intended to call upon the resourcefulness of the patient to meet the needs of the case.

A Case for Diagnosis.—Dr. LOUIS CASAMAJOR presented this patient, a man, 32 years old, a driver, who was admitted to the New York Neurological Institute on March 26, 1914, complaining of weakness and cramps in his left arm and cramps in his abdominal muscles, the trouble dating back for eighteen months. With the exception of an attack of pneumonia five years ago, his previous history was negative. He denied syphilis. About a year and a half ago he had a sudden attack of pain in the left arm. He visited a

clinic, where he was told that he had wrenched the arm and was advised to get an easier job. From this time on attacks of cramp-like pain occurred at shorter intervals, and ten months ago he noticed that his arm was becoming weak. Whenever he raised his hand to the back of his neck there was a severe, cramp-like pain in the biceps. Six months ago he began to suffer from similar cramp-like pains in the upper abdominal muscles whenever he bent over. These were extremely painful, causing him to cry out and sometimes to fall. Examination of the eyes showed nothing abnormal excepting a slight strabismus, a matter of long standing. All the deep and superficial reflexes were active and equal. On the left side there was some atrophy of the shoulder girdle and marked atrophy of many of the smaller muscles of the hand. In the affected arm and forearm there was about one inch of atrophy. When the patient first came under observation the arm and shoulder muscles showed many involuntary, lightning-like, disseminated muscular contractions, affecting chiefly the muscle bundles, and seldom strong enough to move a joint. Later these were not noticeable. When he raised the elbow and placed both of his hands behind his neck there occurred a severe tonic contraction in the left biceps which was quite painful and had to be overcome by forcible extension at the elbow. The electrical reactions showed extreme hyperexcitability of all the muscles of the left arm, with the myotonic reaction in the left biceps. The urine was negative, as were the Wassermann and spinal fluid tests. Under calcium lactate, which was given by the advice of Dr. Walter Timme, the patient had improved, only to have a recurrence of his symptoms when the drug was intermitted.

Dr. I. Abrahamson said that at a recent meeting of the Section on Medicine of the New York Academy of Medicine Dr. Jesse G. M. Bullowa presented his case as one of myotonia atrophica, and this case apparently belonged to the same category. The speaker thought that the combination of muscular atrophy and myotonia was much more common than was generally believed; he regarded myotonia as a symptom found in connection with many diseases, especially in cord diseases, including syringomyelia. He distinguished two types of the disease, characterized by progressive muscular atrophy and myotonic; a familial type, occurring commonly in more than one member of a family, previously named myotonia atrophica, and an acquired type. It was to the latter group that both Dr. Bullowa's and Dr. Casamajor's cases belonged. In the former case the earliest symptom noted was a disagreeable tonic muscular spasm of the abdominal muscles when the patient tried to rise from bed in the morning. This spasm soon relaxed, and the later abdominal movements were free. Subsequently a progressive wasting of the shoulder muscles developed. Examination showed decided muscular atrophy; myotonic electrical reactions and polar changes in the wasted muscles. Fibrillary twitchings were present, but not as widespread nor as marked as in Dr. Casamajor's case. In the latter case, no single segment of the cord could be held responsible for so widespread a disturbance. The speaker believed that there was a progressive change in the interior horns in these cases. Cases of myotonia atrophica had been described associated with atrophy or maldevelopment of the testes; this was present in Dr. Bullowa's case, and it was proposed to note the effect of the administration of testicular extract. The result of the treatment could not be seen at this early date.

Dr. I. Strauss said that while he was inclined to agree with Dr. Abrahamson, he would take exception to the statement of Dr. Casamajor that in dealing with a condition of this kind there was any necessity for assuming that it was attributable to any particular segment of the cord or to changes in the anterior horn cells. It was probably due to some change in the muscle itself. What that change was he did not know, but certainly in myotonia atrophica there was nothing to prove that it was a disease of the cord. The pain in these cases was similar to that complained of in muscles where there are circulatory disturbances, such as is not infrequently observed in the lower limbs.

Dr. Casamajor, in closing, said that with such a distribution of symptoms, involving both the abdominal muscles and the shoulder girdle, the lesion, of course, could not be limited to any particular segment of the cord, but this did not preclude the possibility that they were due to spinal cord conditions. Dr. Strauss said he could not see how a lesion of the anterior horns could bring the muscle into such a state of spasm; still, we saw that in toxic conditions, such as strychnia poisoning, which affects principally the anterior horn cells. Dr. Casamajor said he was interested in the reference made by Dr. Abrahamson to the possible relationship between this condition and atrophy or maldevelopment of the testes. In this case calcium lactate was advised by Dr. Timme on the assumption that the muscular contractions might be due to calcium starvation. When the patient first came under observation, he was incapacitated on account of the spasm of the muscles, and after taking five grains of calcium lactate, four times daily, for a week, he was so much better that he was able to return to work. After a fortnight he gave up taking medicine, and within two weeks he was so tied up with cramps that he had to discontinue his work. He was again put on calcium lactate, with an immediate improvement and the disappearance of his fibrillary twitchings.

The Infantile Roots of Masochism.—Dr. Paul Federn of Vienna presented a paper on this subject. He said it was Freud who established methodical psychoanalysis, and with its help found unconscious processes underlying most neurotic symptoms. These unconscious processes had their particular laws and mechanisms, and they could neither be subsumed to the physiological processes nor to conscious psychic activity. In the unconscious, instincts found a more unbroken representation than in the conscious psyche, and of these, the sexual instincts played the foremost part. We were all familiar, Dr. Federn said, with the cases of declared masochism and the sexual perversities reported in many publications, particularly in Krafft-Ebing's standard work. There were individuals who obtained sexual pleasure from processes which seemed far removed from the ordinary procretive instincts. The declared masochist found his sexual satisfaction in his moral slavery to some overwhelming compulsion, or his fancied deprivation of all will, or in being bound or tortured, or forced to vile and inhuman services. Frequently there was combined with masochism also passive algolagnia, *i.e.* sexual pleasure gained from physical pain. In subjecting such an individual to psychoanalysis, that is, in retracing the chain of forgotten or repressed events and images that had developed in his masochism, one would invariably discover that the sexual perversity dated back to childhood. Binet had suggested the generally accepted theory that such children had been injured by some painful trauma in moments of sexual excitement and the child had then combined the sensations of pain and sexuality so vividly that this association could not be destroyed by the later trend of normal sexual development. Psychoanalysis, however, had discovered deeper causes for these so-called autosuggestions. In many cases, masochistic fancies had already preceded the trauma; in others, the child had neither suffered any cruel experiences nor had it been influenced by the sight of unusual cruelty. Many of these individuals declared that these masochistic fancies first arose in them suddenly and spontaneously, without any external suggestion. Later, they were surprised to learn that other people experienced the same abnormal desires, and it was then that they discovered the sexual origin of their perversities. Masochism could frequently be traced back to infancy. This explained why the adult masochist found sexual gratification in the fancies and terrors and desires of his nursery days. In this connection were characteristic his fancied relations to the strong-willed and tyrannical teacher, the unjust or cruel governess, the sensation of being ridden upon or treated like some domestic animal, and the memory of his training as a very small child in hygienic cleanliness. Usually, the masochist indulged no further than fancies. Only a comparatively few masochists tried to realize their perverse inclinations. For the most part they were content with their imaginings, ever widening, and making them more fantastic and increasing to a higher and higher degree their passive slavery to some irresistible and compelling power. Investigation had proven that the sensation of pain was not essential to masochism. What was essential was the idea of passivity. While the normal male instinct tended to action, the masochist found pleasure only in passive acceptance. Dr. Federn said we but rarely found masochistic tendencies without sadistic tendencies in the same individual. Usually, both were combined in a more or less degree in normal as well as in neurotics, and in sexual perverts. The differentiation was only in the quantity of each factor, and from typical cases of combined masochism and sadism he had arrived at a number of important

conclusions. He had found that the individual who could assume both sexual attitudes not only played the active and passive rôles in his fancies, but experienced some of the characteristic sensations of both sexes in his genital organs. He had discovered, and other psychoanalysts, particularly Freud, had corroborated his findings, that the sadistic sensations were localized in the glans and the anterior portion of the penis, while the masochistic sensations were usually localized in the perineum and scrotum. The localization of sexual sensation in the perineum and scrotum could only be explained by the probable fact that this part was homologous to the female external organ. The speaker said that in extreme cases of sadism and masochism he had found that the individuals had suffered from some painful affection of the genital organs in childhood, Balanitis, phimosis and paraphimosis, eczema, urethritis, cystitis, or the presence of worms, according to his observation, might have an influence on these sexual perversities. Especially, cases of extreme algolagnia may have had their origin—without conscious knowledge of the sufferer—from smarting affections in the undeveloped organs, and to those interested in the mechanism of dreams it would be a valuable proof in that connection to know that even perfectly normal adults might have sadomasochistic dreams when they acquired some painful disease of the genital organs, like gonorrhea. Being an inhibition of virile sexual activity, masochism in itself was a disturbance of the normal sexual life, and its symptoms would be found in all degrees, varying from a slight reduction of the libido to sexual anesthesia, and even to true psychic impotence. As the masochist was inclined to assume a passive attitude in affairs of life, one could observe the effects of his masochistic tendencies in his undertakings. Very few masochists submitted to their sexual abnormality and to their instinctive passivity without fighting. Most of them felt deeply humiliated by their childish and absurd method of sexual gratification. The more refined and otherwise normal a man was, the more depressed he became by this conflict. Moodiness and continuous depression were therefore the usual neurotic consequences of intense masochism. To sum up briefly, the four chief consequences of masochism were impotence, depression, aboulia, and so-called neurasthenia. As to the treatment of this condition, the prophylactic was the most important. In most cases the neurosis could be traced back to a comparatively slight disturbance in infancy and childhood, such as infantile fear, extreme sulkiness, incorrigibility, bad habits, sudden inability to learn, self-isolation, and brooding. These different phenomena called for different lines of treatment, especially when we knew that the child at this time was passing through a period of sexuality. That was why it felt everything more intensely and was excitable, with a secret sense of guilt, and every reasonable and known method of mitigating sexuality should be employed in such cases. Among these might be mentioned diet, sport, and, in cases of physical illness, medical treatment. Children frequently failed to mention pain in their genital organs, and it was of vital importance to overcome this secrecy which upset the child. Again and again we were distressed to learn by psychoanalysis of the great and avoidable suffering of neuropathics in childhood, when the torture of abortive sexual expression was much increased by the contempt and harshness or the indifference of their guardians. By using Freud's method of psychoanalysis the neurologist would gain a deeper knowledge of the origin of mental diseases and of the child's mental development, and by deepening and spreading that knowledge the road would be cleared for the progress of mental hygiene.

Dr. A. A. Brill said that through Dr. Federn's previous published writings on this subject, he had become acquainted with his views, and in the main he agreed with him. More particularly, he could corroborate in a few cases from personal clinical observation the locations given by Dr. Federn. In connection with this subject, Dr. Brill reported the case of a man, 43 years old, a successful politician and very forceful man, who had held the highest political position in his own State, who for years had suffered almost nightly from fancies of a masochistic nature, lasting several hours, before he could fall asleep. Investigation showed that this man, who in his daily life was regarded as a big fighter, was just the opposite in his fancies. He was burdened by hereditary weakness, having had a very brutal mother and a sadistic teacher.

Dr. C. P. Oberndorf said that he had been much interested in the fact that Dr. Federn appeared to emphasize an organic basis for masochism, attributing it to a hyperirritability in the region of the perineum. If this tendency was considered primarily one of an anomaly in development, Dr. Federn's view was similar to that which Ferenczi recently adopted in regard to homosexuality. In a very enlightening discussion of homosexuality in the male Dr. Ferenczi claimed that the active form of homosexuality was a neurosis, while the passive form was due to an intermediate organic sexual development and therefore not amenable to psychoanalysis. He had never cured a case of passive homosexuality, nor for that matter completely cured the neurotic or active form of homosexuality. The speaker asked how far, in view of Dr. Federn's organic conception of masochism, he had been able to influence his masochistic patients by psychoanalytic treatment?

Dr. Abrahamson said he was rather inclined to doubt the localization of masochistic and sadistic sensations, as pointed out by Dr. Federn, as we frequently saw both varieties in the same patient. He recalled one case which he saw in Munich, that of a medical student apprehended for flagellating a young boy. In this patient, both perversions were present. In the absence of partners for his activities, he resorted to symbolic representations of these acts, so that at one sitting he would depict an entire week's program, sadism alternating with masochism; he seemed to revel in his diagrams and asserted that the sexual gratification he received therefrom was only a little less pleasurable than the actual. Surely in a case of this kind localization of sensations was out of question.

Dr. Jelliffe said he was very glad that Dr. Federn had called attention to the prophylactic aspect of this subject of masochism and in tracing these sensations back to childish habits. The desire of the child to lock himself up, the common expresion, "I will die some day and you will be sorry," were probably familiar to us all, and even into adult life we carried similar types of reaction that something might happen to us whereby somebody else would suffer. We get very sorry for ourselves. The style of French literature referred to by Dr. Federn had its prototype in this country in the tales of Nick Carter and Deadwood Dick, etc. Many examples of sadism and masochism could be observed in our every-day life, in the cruel father, the overtender attitude of the mother, the exaggeratd sympathy poured out on criminals, the misdirected efforts of antivivisectionists and antivaccinationists, and perhaps the prevention of cruelty to animal advocates and even the antisuffragettes belonged in the same category.

Dr. Federn, in closing, said he quite agreed with Dr. Brill that many masochists were energetic fighters in their particular social and business spheres. This was especially true of some individuals who, yielding to their abnormal sexual desires, freed themselves from the passive attitude in their general life. To enter fully into the question that Dr. Oberndorf had raised would mean to open the discussion of the whole problem of psychoanalytical therapy. We were far from able to make normal every case of masochism. The aim of medical treatment was to free the individual from suffering; not to change his character. We all knew of many worthy people, quite normal in other respects, who had sadomasochistic tendencies which they were able to govern or to endure without suffering. If by treatment we achieved this state in our patients, we had done our medical duty, but in many cases we were able to go beyond this point, and to combine with it some educational influences. Many patients who disliked their sadomasochistic tendencies became normal sexually after psychoanalytical treatment. By making conscious many unconscious roots or fixations of abnormal sexuality, and by removing the unconscious resistances to normal sexuality, psychoanalysis led such patients to return to the line of normal development, which meant that following the sadistic and masochistic periods in childhood, normal sexuality became dominant. In many cases the masochist must go back to the preceding sadistic period and live a renewed sadistic attitude during the treatment, but an adult who developed will power and was aided by the psychoanalyst might succeed in sublimating his sadism, and shifting it to his social work. Such individuals developed by treatment a much greater energy in social life than they ever had before. In many cases, however, where the patient's environment was unfavorable or his constitutional traits fixed, no real cure was pos-

sible. Dr. Abrahamson had mentioned a very interesting case from Kraepelin's clinic, and the speaker said he agreed with him that it was a remarkable fact that in this case the patient himself produced his symbolic fancies. The case mentioned corresponded in nearly every detail to the description he had given, as this related to the combination of both perversities. All these symptoms seemed very complicated until we found the key to the trouble. Most probably, had Dr. Abrahamson's attention been directed to that point, he would have found the difference of localization and sensation corresponding with the sadistic and masochistic attitudes, so far as the first sensation was active in the anterior and the other in the posterior part of the organ.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

SURGICAL OPERATIONS WITH LOCAL ANESTHESIA. By A. E. HERTZLER, M.D. Cloth; illustrated; 205 pages (2). Published by The Surgery Publishing Co.

PROGRESSIVE MEDICINE. By H. A. HARE, M.D. Paper; Vol. III; illustrated; 339 pages; $6.00 per annum. Published by Lea & Febiger.

FOCAL SYMPTOMS IN GENERAL PARALYSIS. By C. M. CAMPBELL, M.D. Paper; illustrated; 138 pages; price $1.25 net. Published by G. E. Stechert & Co.

DENTAL ANATOMY. By CHAS. L. TOMES, M.D. Cloth; illustrated; seventh edition; 616 pages; price $4.50 net. Published by P. Blakiston's Sons & Co.

MUNICIPAL ORDINANCES, RULES, AND REGULATIONS PERTAINING TO PUBLIC HEALTH. Paper; 570 pages.

THE VACCINATION QUESTION. By C. K. MILLARD, M.D. Cloth; illustrated; 243 pages; price $6.00. Published by H. K. Lewis.

OUTLINES OF ORGANIC CHEMISTRY. By F. J. MOORE, Ph.D. Cloth; second edition; 325 pages. Published by John Wiley & Sons.

PRACTICAL BANDAGING. By E. L. ELIASON, M.D. Cloth; illustrated; 124 pages. Published by J. B. Lippincott Co.

THE CARE OF THE SICK ROOM. By E. G. CUTLER, M.D. Cloth; 54 pages. Published by the Harvard University Press.

INTENSIVE TREATMENT OF SYPHILIS AND LOCOMOTOR ATAXIA BY AACHEN METHODS. By REGINALD HAYES, M.D. Cloth; 63 pages. Published by Balliere, Tindall & Cox.

Therapeutic Hints.

Cannabis Indica in Therapeutics.—H. A. Hare points out that the use of this remedy is handicapped by its frequent lack of power. Only a preparation which has been physiologically tested should be used. The doses are: solid extract, ¼ to ½ grain; fluid extract, 4 to 20 minims; and tincture, 15 minims to 1 dram. Cannabis indica is a valuable addition to cough mixtures, as it quiets the "tickling in the throat," and does not depress or constipate as does morphine. In migraine a valuable remedy is tincture of gelsemium, 20 drops, followed by fluid extract of cannabis indica, 10 to 20 drops. In some susceptible patients the above dose of gelsemium may produce great depression. Cannabis indica quiets the tremor in paralysis agitans and affords great relief in spasm of the bladder due to cystitis or nervousness. It is useful in the headaches of the menopause and in those due to retinal asthenopia.

Hare has found the following efficient in gastralgia and other abdominal pains:

℞ Tincture of capsicum, ʒ j
Tincture of cannabis indica, ʒ ss
Deodorized tincture of opium, ʒ j
Tincture of chloroform, ʒ j
Compound tincture of lavender, q.s.ad ʒ iv

S. Teaspoonful every hour until pain is relieved. Cannabis indica has been found valuable in the treatment of dysmenorrhea and of nonorganic sexual impotence.—"Practical Therapeutics."

The Avitaminoses and Their Treatment.—H. Stassano defines the avitaminoses as diseases resulting from a deficiency of vitamines in the diet. The vitamines are complex crystalline substances belonging to a chemical group hitherto unknown. The nitrogen is not combined in the amine radicle and can be extracted only in part by the Kjeldahl method. The characteristic syndromes of the avitaminoses are classified as follows: (1) The syndrome of degeneration of nerves with paralyses and contractures; (2) the cardiac syndrome with dilatation of the right heart accompanied by dyspnea, cyanosis, and oliguria; and (3) the syndrome of anasarca, hydropericardium, hydrothorax, and ascites; all of these three syndromes belong to the group of cases properly called beriberi. (4) The classical syndrome of scorbutus. (5) The syndrome of pellagra. In all of the above conditions the following articles of diet which are rich in vitamines have been found to be of curative as well as of prophylactic value; human milk, fresh cow's milk, butter, cheese, yolk of egg, beef juice, fresh tomatoes, fresh legumes and soups containing them, fresh fruits or their juices, the sauce of stewed fruits, whole corn or wheat bread, unpolished rice, slightly roasted beef, fresh yeast, extracts and preparations of yeast, and codliver oil—*La Quinzaine Thérapeutique.*

The Treatment of Urticaria.—Bouchard states that in addition to the removal of the cause and the use of a lotion of two parts of warm water and one part of vinegar, the following lotion is quite effective:

℞ Cocaine hydrochloride,
Chloral hydrate,
Resorcin, āā, 2 grams.
Glycerin, 6 grams.
Alcohol, 40 grams.
Cherry laurel water, 60 grams.
Distilled water, 90 grams.

TOXIC DISEASES OF THE NERVOUS SYSTEM, WITH REPORT OF CASES.*

BY EDWARD D. FISHER, M.D.,

NEW YORK.

MY object in introducing this subject at this meeting of the New York State Society is to bring into consideration the large number of cases which come under every one's observation of diseases of the nervous system, which both in diagnosis and treatment are indefinite and unsatisfactory. Those cases, in fact, which do not fall under the recognized forms of cerebral and spinal disease, such as cerebrospinal meningitis, poliomyelitis, diphtheria, or tetanus—cases, however, which are very serious in their manifestation and often have a fatal issue. I believe they belong to the same class as the above-mentioned diseases. They are of bacteriological origin, as yet of an unknown nature, in which toxins are given off which align themselves to the cells of the nervous system, causing impairment or destruction of the nervous elements. The more we study these indefinite cases the more probable seems the conclusion that we have to deal with many germ diseases and their accompanying toxins, which as yet remain unclassified, but which in their clinical manifestations resemble in every respect, *i.e.* in character of onset, the better known infectious diseases with their toxins.

Disease due to toxins differs from that consequent on infection in that the latter is communicable.

By infection we understand the entrance into the body of living agents, capable of multiplication, commonly microbes. A toxin is incapable of multiplication; it is a bacterial product (Hektoen). In a strict sense toxins are soluble products of bacterial animal and vegetable origin. They are of unknown chemical structure. They resemble organic ferments. The toxic action of bacterial or other toxins (*i.e.* lead, alcohol) is dependent on the chemical union of the toxin with the cells of the body. The nervous system is especially susceptible to this assimilation. It is not surprising, therefore, that we find disease of the nervous system resulting from the various infectious diseases and their toxins. We know that it is the toxin rather than the microbe itself that causes the clinical manifestations.

This is well demonstrated in diphtheria and tetanus. The dead bacilli introduced into the system produce all the symptoms of the disease, showing that it is the end product, the sterile chemical solution, which causes the cellular changes, by the cell absorption of the definite poison. Syphilis is an excellent illustration of this view. The spirochetes, as we now know, remain active and are demonstrable not only in the early stages of syphilis but in the later manifestations, as in tabes and general paresis. Still it is not the direct action of the living spirochete which causes the symptomatology of syphilis, but the chemical poison thrown out by the syphilitic virus, even after its destruction. In the present treatment of this disease, we probably do not succeed in killing the active agent, *i.e.* the spirochete; we simply control its multiplication, leaving it ever ready, when not under the controlling influence of mercury and arsenic, under favorable circumstances to take on active increase.

A simple illustration of a similar condition is seen in malaria. Quinine is the only agent effective in this condition; still it does not kill the plasmodium, it simply arrests its development under proper conditions, and on the withdrawal of the quinine we have again its clinical manifestations in the form of chills and fever.

Influenza (grippe) demonstrates the effect of a toxin on the nervous system possibly more clearly than any infectious disease due to a microbe of inferior virulence. Here we see the sudden onset of some infection. The system suddenly collapses; various organs are affected, at times the lungs, the heart, the special sense organs, and sooner or later the nervous system; this may, indeed, be the first involved; certainly it rarely escapes, showing that the toxin of the bacillus of influenza has aligned itself to the cells. We find its manifold symptoms in disease of the meninges and of the brain and cord—involvement of the anterior horns, a form of poliomyelitis not dependent on the specific germ discovered by Flexner.

I think we all see such cases in which the paralysis is not extreme, and in which often a complete recovery takes place (see case of Guardis). Again we may have myelitis, usually also not of the acute form, but gradually progressive if the cell assimilation of toxin has been extreme. These cases later by secondary degeneration in the nerve tracts of the spinal cord explain our cases of chronic myelitis, or the so-called cases of primary lateral sclerosis.

I have spoken so much at length on influenza infection because it seems to represent the indefinite class of toxic diseases. We have now a rather complete knowledge of the specific germ in cerebrospinal meningitis and in poliomyelitis. It is still unknown for myelitis and Landry's paralysis. These both represent clinical pictures which suggest a distinct poison microbic or toxic in character.

As I have previously said, we all observe cases which do not fall completely into any of the classes clinically. I will now present some such cases which have been under my observation.

The first case which I shall refer to is one which I reported as that of Landry's paralysis or acute

*Read before the First District Branch of the Medical Society of the State of New York, October 8, 1914.

ascending paralysis, at the last meeting of the American Neurological Association. It is interesting as it was observed from the beginning and followed to its fatal termination, an autopsy fortunately being obtained. Most authors agree that Landry's paralysis is of infectious origin and attempts have been made to isolate a specific organism, but without success. In the literature of the subject, which is considerable, various lesions of the nervous system have been recorded, affecting the peripheral nerves, the spinal cord, the medulla, and the brain. Leyden and Goldscheider hold that it may assume any or all of these forms.

The first case was observed from the onset and a careful post-mortem examination has been made. The patient was a male, 15 years of age, whose previous history was negative. On September 27, 1913, he complained of pain and weakness in the lower extremities, which increased in severity until October 11, when he was admitted to St. Vincent's Hospital, New York, in the service of Dr. Constantine J. MacGuire. Examination of the heart and lungs and abdominal organs was negative. There was paralysis of the lower extremities, with loss of reflexes and tenderness over the larger nerve trunks. There was no anesthesia. The weakness gradually extended to the upper extremities, with loss of power, which in the course of a week became complete in the hands and arms. On October 29 there was difficulty in swallowing and complete paralysis of the muscles of the right eye and of the superior oblique of the left eye (Dr. Kelly). On November 7 there were dyspnea and difficulty in swallowing. All of these symptoms gradually increased in severity, and death occurred on November 21 from respiratory failure.

The autopsy, macroscopically, showed intense congestion of the cord: no other lesion. Microscopically, there was an interstitial neuritis of the sciatic nerve and congestion of the anterior horns, without perivascular infiltration or meningeal involvement. The medulla showed involvement of the cranial nerve nuclei and degeneration of the axis cylinders for a short distance from the cell body. The whole picture differentiated it from poliomyelitis. The brain, at the time of this report, had not been examined. The microscopical study of the case was made by Dr. John Larkin.

Conclusions.—We have here, therefore, a case of ascending paralysis, with attending neuritis, which followed the usual course of extension, later involving the upper extremities and the bulbar nerves, resulting in respiratory failure. The pathological findings are definite, involving both the peripheral and central nervous system. The course of the disease was longer than that usually described, extending over six weeks, but otherwise the case was typical in its manifestations.

The second case was that of a female, age 28 years, whose previous history was negative. Occupation, nurse. July 5, 1914, she was admitted to the hospital ward complaining of pain in the left side of the chest. July 8, her temperature rose to 105°F. and she had severe headache, much vomiting, and rigidity of the neck. The white blood count was 14,000 with polymorphonuclear cells 86 per cent.

July 10 there was paralysis of the lower extremities, loss of reflexes, tenderness on pressure over nerves and muscles. Blood culture was negative.

July 11, anesthesia extended to the umbilicus; there was rigidity of the neck, but no Kernig's sign. At 11 P. M. lumbar puncture was done by Dr. Zimmerman. The fluid was clear and of moderate pressure. The findings were most remarkable. There were 151 cells to the cubic centimeter, with deeply stained nuclei, looking like endothelial cells, and a few lymphocytes and polymorphonuclear cells. Fehling's solution was not reduced. Cultures in broth and agar were negative. Cultures of the urine were also negative. The condition of the patient became worse and death occurred on July 16 from cardiac failure, the patient remaining in a stuporous condition. The eye grounds had shown a beginning choked disc. All cultures were negative. No post-mortem was obtained.

Here we evidently have a distinct infection of an unknown character, involving the meninges, as shown conclusively by the rigidity of the neck, and the increased cell count in the spinal fluid. The neuritis of the lower extremities, a loss of reflexes, and ascending paralysis suggest a condition of the nature of Landry's paralysis.

A third case which from the symptoms suggested either some infection involving the membranes at the base of the brain, or basal syphilitic meningitis, is of interest, as the post-mortem revealed something entirely different.

The patient was a male, age 36 years, who complained of headache and dizziness on admission to the hospital. The principal symptoms were paralysis of the sixth cranial nerve, with internal strabismus and diplopia, and a staggering gait, suggestive of cerebellar disease. The patient had continuous headache, the eye grounds showed choked disc, but the vision was not impaired. The examination of the blood and spinal fluid showed a negative Wassermann. The patient died in coma. A diagnosis other than basilar meningitis of unknown origin was impossible. (Tuberculosis was also excluded.) Without a post mortem this might well have been classed as an infectious disease of unknown character.

The autopsy showed, however, a sarcomatous basilar meningitis. Small bodies resembling tubercles were found scattered over the meninges and the base of the brain, and two small tumors were found in the frontal lobes, incapable of causing any symptoms. There was also a secondary involvement of the liver and spleen.

A fourth case I will only briefly refer to. The patient was a male, age 40, with a specific history with Wassermann reaction. The onset of the symptoms, however, was sudden, resembling an acute ascending paralysis with neuritis. The upper extremities were not affected, but the disease extended to the cranial nerves causing almost complete ophthalmoplegia and ptosis, and later difficulty in swallowing and the characteristic nasal tone of speech seen in bulbar paralysis. There was a gradual but incomplete recovery at the time the patient left the hospital.

This case did not correspond to syphilis of the nervous system nor did it respond to antisyphilitic treatment. There was evidently an acute affection of the nervous system, cord, and bulb, suggesting acute ascending paralysis or poliomyelitis.

Two cases of subacute or chronic myelitis are now under my observation showing paresis of the lower extremities of some months standing, with incomplete anesthesia and vesical weakness with exaggerated reflexes. May not these be due to some toxin?

Possibly we may in the future put many of these cases of myelitis or primary lateral sclerosis down to such agents, especially when, as in one of these cases, there was no evidence of syphilis.

I have brought these cases together, to which I might add many more, to suggest the idea of infection or toxic poison as probably a more frequent etiological factor than has been generally supposed in various diseases of the nervous system. The question of treatment, as long as we are ignorant of the infective agent, is naturally only that of the symptoms, meeting each emergency as it arises. This is exemplified in Landry's paralysis. The importance, then, of the continued work of our research laboratories is thus emphasized.

46 East Fifty-second Street.

The Carriers of Gonococcus Infection.—A. Guépin divides these into three groups as follows: (1) convalescents from an acute gonorrheal infection; (2) cases of chronic infection; (3) those individuals who have no clinical symptoms of Neisserian infection and who deny that they have ever had such symptoms. Rigorous bacteriological examination is necessary.—*Pratique des Maladies des Organes Génito-Urinaires.*

CHOLERA IN THE PHILIPPINES DURING 1913.*

By VICTOR G. HEISER, M.D.,

MANILA, P. I.

DIRECTOR OF HEALTH FOR THE PHILIPPINE ISLANDS.

CHOLERA again made its appearance in Manila on August 24, 1913, after an absence of over two years. The first case occurred in a Filipino who worked as a carpenter at one of the local hotels but who lived at 1060 Calle San Sebastian. It is said that he invariably took his meals at his home. A careful inquiry made at the hotel showed that no guest had arrived at that institution from Hongkong, or any other foreign country where cholera was present, for more than ten days previous. The victim left his place of employment on the evening of August 23, apparently in good health. About noon of the next day he was seized with violent pains in the abdomen which later in the afternoon increased in severity. In addition he had severe cramps in the muscles of the calves and forearms. There was no diarrhea. A physician was called, who reported that by evening the case presented many of the clinical symptoms of cholera, and he ordered the patient transferred to the San Lazaro cholera hospital. Upon his arrival at that hospital, about 10 P.M., he was in a moribund condition and died a few minutes later. At the autopsy, which was held on the morning of August 25, typical lesions of cholera sicca were found in the intestines. The lower bowel contained a large amount of hard, formed feces. A rice-water-like fluid was found in the ileum, cultures from which, prepared in accordance with the procedure recommended by the International Conference of Public Hygiene, resulted in the isolation of the true cholera vibrio.

Another case of cholera came under observation on August 25. It occurred in a Filipino who was employed as a cook by a British family in Caloocan, which is a suburb of Manila and a number of miles removed from the first case. No connection whatsoever could be traced between them. This victim gave a history of having been ill with diarrhea, and having cramps in the muscles of the extremities for a period of about a week previous, and as his employer thought that he was malingering he was dismissed. The next day (August 25) after this occurred he was found in a house in the San Lazaro district and then promptly transferred to the San Lazaro cholera hospital. The records of that institution show that he had rice-water stools, cramps in the muscles of the legs, suppression of urine, husky voice, subnormal temperature, and other well-recognized symptoms of cholera. Cultures made from his stools resulted positively for cholera.

The next case came under observation on September 13 and was in the person of a carpenter who worked and lived in the district of Malate. This address is several miles removed from where the previous cases had occurred and no connection could be traced with them. During the week ended September 20 there were three cases; for the week ended September 27, five cases, and for the week ended October 4, eight cases.

The first eight cases occurred in widely separated sections of the city and a most careful investigation failed to trace any connection whatsoever between the cases. After that, however, there were a number of instances of contact infection. A most noteworthy occurrence in connection with the outbreak was the fact that cholera vibrios were found in the stools of the contacts in many instances, as may be seen from the following table:

Case No.	Contacts Examined	Found Harboring Vibrios	Found Harboring True Cholera Vibrios	Percentage of Persons Examined Harboring Cholera Vibrios	Toilet Facilities

An inspection of the premises in which cholera cases occurred showed that there was apparently more or less direct connection with the disposal of feces and outbreaks of the disease. The foregoing table also shows that the disease in over 80 per cent. of the cases occurred on premises in which there was no modern plumbing. This table further shows that of seventy-two contact groups examined, forty of them were vibrio carriers of some kind, and twenty-nine were true cholera carriers.

These results illustrate in a very striking manner the necessity for proper laboratory facilities if a campaign against cholera is to be intelligently directed.

Later, the disease made its appearance in Orani,

*Read at a meeting of the Manila Medical Society held March 2, 1914.

Orion, and Pilar, in Bataan Province; in Bocaue, Meycauayan, Bulacan, Balinag, and Malolos, in Bulacan Province; in Bacoor, Cavite, Rosario, and Santa Cruz, in Cavite Province; in Angeles, Guagua, Macabebe, Mexico, San Fernando, Santa Ana, and Sexmoan, in Pampanga Province; in Asingan, Dagupan, Lingayen, Santa Barbara, and Urdaneta, in Pangasinan Province; in Caloocan, Fort McKinley, Las Piñas, Navotas, Parañaque, Pasay, Pasig, Pateros, San Felipe Neri, San Pedro Macati, and Taguig, in Rizal Province. During October the disease suddenly made its appearance in Cebu and Opon, in Cebu Province, with a total of three cases and two deaths. The disease here, as in former places, was apparently sporadic and could not be traced to any outside source and is of special interest because no cholera was known to have occurred in that province for more than three years. Banga, Calivo, Lezo, and New Washington in Capiz Province became infected during November. The origin of the infection could not be traced.

The diagnoses were microscopically confirmed in each town in which the disease made its appearance.

It was possible to eradicate the disease within a comparatively few days in any town in which it appeared in each instance in which prompt measures were taken with the first cases. The co-operation received from the public this time in reporting cases promptly has been of great assistance, and it is believed that this co-operation was largely secured on account of the less drastic measures which were employed. For instance, no quarantine measures were imposed except to quarantine the house in which the case of cholera occurred when it was impossible to transfer the patient to a hospital. It is believed the good-will gained by this procedure more than offset the risk which was run by not imposing more extensive quarantine methods. The general populace among whom cholera appeared made practically no objections to the methods which were employed. There was one notable exception, however, to the foregoing, and this was in the province of Capiz. It seemed impossible to secure the co-operation and assistance of the public there and the efforts of the sanitary officials were much hampered by the spread of rumors that the latter were poisoning the wells and that the agents of the Government did not have at heart the well-being of the people.

From the best information obtainable, there was no cholera anywhere in the Philippines since October, 1911, and a careful investigation fails to show that the disease was introduced from a foreign country. It has been the practice of the Quarantine Service during the past two years to examine the stools of all steerage passengers and of those who come from cholera districts from foreign countries on all incoming vessels, and for more than a year previous to the appearance of cholera in Manila no passengers harboring the cholera vibrio were found. The appearance of the disease, often simultaneously, in widely separated sections and the failure, after most careful investigation, to trace the infection would appear to furnish evidence that this outbreak was not caused by the disease being introduced from a foreign country. After cholera once established itself in a town, sometimes an infection could be traced to a previous case, but as a rule they occurred in widely separated barrios that had no common water or food supply and where no contact by persons or insects could be traced with previous cases.

The record of the outbreak, with the exception of Capiz, indicates that the disinfecting and other sanitary measures were promptly and effectively applied, because it was very rare to have more than one case in a house, or even a district, unless the cases were taken all at the same time.

From the foregoing it is apparent that the origin of the present cholera outbreak cannot be definitely traced. There is considerable evidence from an epidemiological standpoint that cholera carriers may always be present in the Philippines and that perhaps the organism passes through a cycle during certain stages of which it may perhaps not be recognizable by present laboratory methods, yet such organisms, when they find their way at another stage of their cycle into the intestines of a more susceptible individual may produce cholera. The increase and decrease in virulency also very probably play an important part as to whether an epidemic results. If the sanitary measures employed prevent the passage of the organism through the intestines of a number of different persons, the virulence remains low and the disease soon disappears.

In Manila to December 31, 1913, there have been 210 cases, of which 137 died. In the provinces there were 698 cases, with 510 deaths. Of the provincial cases the great number occurred in Capiz, which was a province in which no effective co-operation could be secured. It may be of interest to note that in the outbreak of 1902 there were during a similar period 3,033 cases and 2,348 deaths in Manila, and 12,121 cases and 8,923 deaths in the provinces.

Measures Employed to Combat Cholera.—The whole campaign was directed toward the prompt disinfection of the stools and vomited matter of the sick and of the carriers. Briefly, this was accomplished by isolating the sick and the carriers in cholera hospitals or other quarters, and where this was not possible by having their stools passed directly into receptacles which contained disinfecting solutions. In communities in which cholera appeared, prompt steps were taken to dispose of the excreta of the entire population in a safe manner. On account of the very prevalent custom among the masses of eating with the fingers from a common receptacle and on account of the personal habits of the people, strong recommendations were made that everyone in an infected district wash his hands in a 1-1000 bichloride or other disinfecting solution before taking food. Water and food supplies were safeguarded. A campaign of education and other measures were carried out as in previous outbreaks, mention of which is made in more detail in previous annual reports of the Bureau of Health.

At the Bureau of Science considerable work is being done in order to ascertain whether flies, roaches, and other insects may be responsible for carrying the infected dejecta to food, and much evidence is accumulating to show that in all probability infection takes place at times in this way. It is believed that the measures outlined above with regard to the disposal of human excreta probably prevented water infection, and for that reason no considerable number of the cases in this outbreak were contracted from this source.

Treatment.—Intravenous transfusion of salt solution was mostly depended upon. More detailed information, particularly with regard to new methods, may be seen in the report of the Chief of the San Lazaro Hospital Division, published in the annual

report of the Bureau for the period ended December 31, 1913.

Recommendations.—The experience in this outbreak has again forcibly demonstrated the necessity for further laboratory studies with regard to this disease. The reasons for the simultaneous appearance of the disease in widely separated sections, if clearly understood, might be of great assistance in combating cholera.

THE FACULTY OF MEDICINE IN THE ORIGINAL UNIVERSITY OF LOUVAIN.

1426-1797.*

By JOHN BETHUNE STEIN, M.D.,
NEW YORK.

"Academia Lovaniensis frequentia nulli cedit hodie, praeterquam Parisinæ, numerus est plus minus tria millia et affluunt quotidie plures."—Erasmus[1].

JOHN IV, Duke of Brabant, together with the civic authorities and clergy of Louvain, petitioned Pope Martin V in 1425 to found a university there, and this pontiff by a bull of December 9, 1425, granted the request establishing the several faculties except that of theology.[2]

The university opened September 7, 1426;[3] the courses of the medical faculty beginning October 8, 1426.[2] In its management the university was modeled after those at Paris, Vienna, and Cologne.[4] There were two chief or official professors appointed by the magistrate of Louvain, on the recommendation of the university, who were not allowed to leave the city without a written permit of the mayor, and could not accept an honorarium for any teaching given outside of the university. Their duty was to explain the teachings of Avicenna and Rhazes.[5, 6]

Little is known of the early history of the medical faculty. In 1864 Monsig. P. F. X. de Ram, rector of the university, found, after much searching, a manuscript which he thought was a copy of the "statutes" (Statuta Collegii Facultatis Medicinæ Studii Lovaniensis) dating from the first epoch of the organization of the faculty of medicine in 1426. This paper has probably been destroyed in the recent sacking of Louvain by the Germans, as it was presented to the Library of Louvain by Eugene van der Beelen. Broeckx, however, thinks these "statutes" are of a later date, viz., 1446, when changes were made in the faculty and the rector of the university began to serve for a period of six months instead of three.[2]

In addition to the two official professors there were doctors who came from Paris and Cologne on the invitation of the magistrate of Louvain, to teach medicine. Of these unofficial assistant or associate professors, one was Dr. Arnoul Bremis (de Brenn), who came to the university in 1426, and another Dr. Godefroid van der Willighen, "who commenced his course Christmas, 1427," and was paid for it by the city.[2]

The first occupant of a chair in the medical faculty at Louvain was Jean van den Eele (van de Neele—van Eele or de Neele), born at Breda and a graduate of the University of Cologne. He was also the first rector of the university.[2]

*In 1817 Holland reestablished the University of Louvain, but the Belgian Government abandoned it in 1834, and in 1835 it was started afresh as a free Roman Catholic University. In 1911-1912 there were 2,725 students in attendance. There were faculties of arts, science, theology, law, and medicine. The library contained over 229,520 volumes.

The following is a list of 41 members of the medical faculty, each of whom was some time also rector, the highest office of the university, from its foundation until 1788, showing the importance then attached to their work, and the esteem with which they were regarded.[2]

Jean van den Eele, 1427, 1431, 1437.
Henri de Coster, 1428, 1429.
Jean Vesale, 1430, 1433, 1438.
Jean Stockelpot, 1432, 1443, 1452.
Henri Scatter, 1435.
Sebert de Neele, 1436.
Nicolas Lamberti, 1435, 1440.
Jean Sucquet, 1441, 1447.
Adam Bogaert, 1442, 1449, 1454, 1459, 1464, 1469, 1474.
Louis de Vettere, 1445.
Jean Spierinck, 1457, 1462, 1479.
Jean de Wellis, 1462, 1467, 1472.
Jean d'Inchy or de Vallibus, 1484, 1489.
Gasper Aegidii, 1487, 1492, 1494, 1497.
Jacques Bogaert, 1502, 1504, 1509, 1512.
Jean Calaber, 1514, 1517, 1519.
Egide de Pape, 1522.
Adam Bogaert, 1524.
Léonard Willemaers, 1527.
Jean de Heems, 1529, 1532, 1535.
Charles Goossens, 1544, 1547.
Jean de Winckele, 1552.
Jacques van der Varent (Varentius), 1562, 1564, 1569.
Jean Blondel, 1574.
Jean Viringus, 1579, 1583, 1587.
Adrien Romain, 1592.
Thomas Fyens, 1594, 1599, 1604.
Jean Storms, 1619.
Gérard de Villiers, 1622, 1627.
Michel Ophemius, 1624.
V. F. Plemius, 1634, 1637, 1647, 1649.
Pierre Dorlix, 1639, 1642, 1652.
Adrien Wolf, 1674, 1677, 1682, 1684.
Jean Herregouts, 1687.
Philippe Verheyen, 1689.
Laurent Peeters, 1692.
Servais Vaes, 1694.
J. B. Raymaekers, 1707, 1709.
U. Narez, 1712.
Rega, 1719, 1722.
Van Leempoel, 1788.

In 1429 Jan Wytinch, or Wytings, Joannes Wesalia, or Vesalius, so called because he was born at Wesel, took an active part in the medical teaching which continued until his death on July 29, 1472. He wrote a work addressed to Pope Eugene IV on the correction of the calendar, and because he was so well versed in mathematics and in astronomy he was invited in 1431 to take charge of the courses of sciences in the faculty of arts at the University of Louvain. Mathematics was usually taught by one of the members of the faculty of medicine.[2, 7] The celebrated anatomist Andreas Vesalius, who was a student at Louvain was a descendant of this Joannes Wesalia.[2]

The three chief officers of the faculty were a dean, a prior, and a judge of appeals.[2]

In 1426, by an edict of Pope Martin V, the priests were permitted to study and teach medicine at Louvain, and it was on account of this privilege that many in the priesthood became professors of medicine.[2]

Pope Eugene IV, hearing that the teachings of Hippocrates and Galen were neglected for those of Avicenna and Rhazes, established in 1443 two new chairs in the medical faculty. The occupants of these chairs were priests and were called "professors in ordinary of the second foundation." They were also called prebendaries because, being canons of the church of Saint Pierre at Louvain, they were paid by the church. Their duty was to explain "alternately during a month" the teachings of Galen and Hippocrates. Later they gave their courses at the same time from July 15 to August 31, and were then known also as "the professors of six weeks."[2, 5, 8]

This church of Saint Pierre, recently destroyed by the Germans when they sacked Louvain, was of interest to the doctor of medicine because

of its close connection with the early history of medicine in Belgium. In it was the famous triptych, painted by Dierick Boudts in 1468—the martyrdom of Saint Erasmus, the patron saint against intestinal diseases, representing the bishop, with an incision in his abdomen from which his intestines are being drawn out and wound upon a crank by two men.

On Saint Luke's day, 1428, there was instituted a series of weekly discussions, by the students, of medical problems. A professor directed the debates of the students at these discussions, which became of great importance in the teaching of medicine. Molanus says of them, "Permittuntur misceri jocosa seriis, sed nec turpia, nec diffamatoria, aut bonos mores offendentia."[2, 9]

Jean Stockelpot, a priest of Louvain, and professor in the faculty of arts in the university, who obtained his licentiate on August 10, 1432, was the first to receive the degree of doctor of medicine from the university on April 26, 1433, and Valerius states that, on May 10, 1433, "he demanded a fellowship in the college or faculty of medicine, 'non obstantibus statutis in contrarium factis aut conditis.'" Following this demand he was made lecturer, and in 1445 he became professor in ordinary in the university, and at the same time canon and prebendary of the church of Saint Pierre at Louvain. Jean Stockelpot was the first professor to be a prebendary of the church of Saint Pierre.[2, 5, 6, 10]

According to the papal bull of Martin V, the government of the university was autonomic, but subject to the Pope and the Duke of Brabant. Attempts against the autonomy of the university were made several times. The first attempt was made upon the death of a canonic professor in 1454, when the government of Louvain attempted to transfer a position of a prebendary of Saint Pierre belonging to the faculty of medicine, to the faculty of theology.[2] This the faculty of medicine objected to and prevented. On January 3, 1476, Charles the Bold, Duke of Burgundy, wished to make some changes in the organization of the university, but because they did not accord with the views of the Pope and the authorities of the university the changes were not made.[11] The faculty gave a proof of its independence in 1476 by refusing admittance to a Dr. Franco, whom the magistrate of the city had selected to succeed a professor, without consulting the faculty.[2]

In 1543 the chairs of the prebendaries were occupied by Arnould Nöot of Halle and Léonard Willemaers. One of these professors absented himself frequently from his lectures, and the other had an associate lecture for him, so that the criticism and censure of the students were excited against them, and because of the brilliant "free teaching" of Jeremie de Drivere (Dryver), or Hiermius Thriverius, the students petitioned the authorities to make the two prebendaryships one and give them to Thriverius. The petition was granted. The two prebendaries were forced to resign and their places were given Thriverius. Thriverius held this position until his death in 1554.[2]

Guillaume Bernaerts succeeded Thriverius, holding the professorship until 1557, when the civic authorities decided to divide the charge as the statutes prescribed. The new professors were ordered to lecture daily, to construe the most useful works, to finish their course at a definite time, and once every week or two one of them was to preside and the other to direct the students at a public discussion of the subjects taught. In addition, they were to give in turn anatomical demonstrations from one to four times a year, according to their ability to procure cadavers, teach of the foreign and domestic medicinal plants, their nature and virtues, and to instruct at the bedside of patients those who were to present themselves for the licentiate examination, teaching them the nature and cause of the diseases and the therapeutic measures to be employed. The civic authorities also decided that in the future a licentiate could not be a professor in the university, but must obtain the degree of doctor of medicine before he could hold a professorship, and that a licentiate in order to obtain this M.D. degree must submit himself for a period of one year to such proofs as this grade demanded."

A licentiate in medicine although he did not possess the legal title of doctor of medicine was, nevertheless, called such, and in 1565 the professors in the medical faculty unsuccessfully requested the university authorities to confer the degree of doctor of medicine upon a student when he became a licentiate because of the expense in obtaining the M.D. degree. At this time the cost to the student who obtained this degree amounted to 1700 florins (Brabant).[2]

Two years of medical study in the university were required before a student was admitted to the examination for the degree of bachelor of medicine, and four years of study before he could take the examination for the licentiate, and the medical faculty in 1435 passed a rule that the student must be eighteen years old in order to take this examination.[2]
